## Preface

This report describes a new programming language called Euclid, intended for the expression of system programs which are to be verified. Euclid draws heavily on Pascal for its structure and many of its features. In order to reflect this relationship as clearly as possible, the Euclid report has been written as a heavily edited version of the revised Pascal report.

Proof rules for Euclid appear in a separate report [London et al 1977]. A Euclid implementation is under development by the System Development Corporation, 2500 Colorado Avenue, Santa Monica, California; information may be obtained from Mr. Hugh C. Lauer.

No implementation of the language has yet been completed, and no Euclid programs of any size have been written. As a result of experience in implementing and using it, changes in the language or its defining report may be made.

This is the third version of the Euclid report; earlier versions appeared in May 1976 and August 1976.

## Acknowledgements

Obviously, we are greatly indebted to Wirth, both for the aspects of the language which are copied from Pascal, and for the structure and much of the wording of the report. We are also much in debt to Hoare's work in the areas of programming language design, axiomatic methods, and program verification. In particular, we have tried to follow his suggestion that "the language designer should be familiar with many alternative features designed by others, and should have excellent judgement in choosing the best... One thing he should not do is to include untried ideas of his own. His task is consolidation, not innovation." [Hoare 1973].

We have consciously borrowed ideas and features from Alphard [Wulf, London, and Shaw 1976], BCPL [Richards 1969], CLU [Liskov 1976], Gypsy [Ambler et al. 1976], LIS [Ichbiah et al. 1974], Mesa [Geschke and Mitchell 1975], Modula [Wirth 1976], and the SUE System Language [Clark and Horning 1973, Clark and Ham 1974]; other languages and suggestions for language features have also undoubtedly influenced our thinking. We have benefitted greatly from comments and criticisms by numerous individual colleagues on previous versions of the language and report, and from the comments of the implementors, especially Lauer.

We are grateful to Prof. Wirth, and to Springer-Verlag, for permission to use portions of the Pascal report [Wirth 1971, Jensen and Wirth 1975] in this report.

Our work has been significantly aided by the Arpanet, which allowed us to maintain effective and rapid communication in stating and resolving problems, in spite of the wide geographical distribution of the authors.

## 1. Introduction

*"There is no royal road to geometry."*

Proclus, *Comment on Euclid*, Prol. G. 20.

The programming language Euclid has been designed to facilitate the construction of verifiable system programs. By a *verifiable* program we mean one written in such a way that existing formal techniques for proving certain properties of programs can be readily applied; the proofs might be either manual or automatic, and we believe that similar considerations apply in both cases. By *system* we mean that the programs of interest are part of the basic software of the machine on which they run; such a program might be an operating system kernel, the core of a data base management system, or a compiler.

An important consequence of this goal is that Euclid is not intended to be a general-purpose programming language. Furthermore, its design does not specifically address the problems of constructing very large programs; we believe most of the programs written in Euclid will be modest in size. While there is some experience suggesting that verifiability supports other desired goals, we assume the user is willing, if necessary, to obtain verifiability by giving up some run-time efficiency, and by tolerating some inconvenience in the writing of his programs.

We see Euclid as a (perhaps somewhat eccentric) advance along one of the main lines of current programming language development: transferring more and more of the work of producing a correct program, and verifying its correctness, from the programmer and the verifier (human or mechanical) to the language and its compiler.

The main changes relative to Pascal take the form of restrictions, which allow stronger statements about the properties of the program to be made from the rather superficial, but quite reliable, analysis which the compiler can perform. In some cases new constructions have been introduced, whose meaning can be explained by expanding them in terms of existing Pascal constructions. The reason for this is that the expansion would be forbidden by the newly introduced restrictions, whereas the new construction is itself sufficiently restrictive in a different way.

The main differences between Euclid and Pascal are summarized in the following list:

**Visibility:** Euclid provides explicit control over the visibility of identifiers, by requiring the program to list all the identifiers imported into a routine or module, or exported from a module.

**Variables:** The language guarantees that two identifiers in the same scope can never refer to the same or overlapping variables. There is a uniform mechanism for binding an identifier to a variable in a procedure call, on block entry (replacing the Pascal with statement), or in a variant record discrimination. The variables referenced or modified by a routine (i.e., procedure or function) must be accessible in every scope from which the routine is called.

**Pointers:** This idea is extended to pointers, by allowing dynamic variables to be assigned to collections, and guaranteeing that two pointers into different collections can never refer to the same variable.

**Storage allocation:** The program can control the allocation of storage for dynamic variables explicitly, in a way which confines the opportunity for making a type error very narrowly. It is also possible to declare that some

dynamic variables should be reference-counted, and automatically deallocated when no pointers to them remain.

Types: Types have been generalized to allow formal parameters, so that arrays can have bounds which are fixed only when they are created, and variant records can be handled in a type-safe manner. Records are generalized to include constant components.

Modules: A new kind of record, called a module, can contain routine and type components, and thus provides a facility for modularization. The module can include initialization and finalization statements which are executed whenever a module variable is created or destroyed.

Constants: Euclid defines a constant to be a literal, or an identifier whose value is fixed throughout the scope in which it is declared.

For statement: A generator can be declared as a module type, and used in a for statement to enumerate a sequence of values.

Loopholes: features of the underlying machine can be accessed, and the type-checking can be overridden, in a controlled way. Except for the explicit loopholes, Euclid is designed to be type-safe.

Assertions: the syntax allows assertions to be supplied at convenient points.

Deletions: A number of Pascal features have been omitted from Euclid: input-output, reals, multi-dimensional arrays, labels and gotos, and functions and procedures as parameters.

The only new features in the list which can make it hard to convert a Euclid program into a legal Pascal program by straightforward rewriting are parameterized types, storage allocation, finalization, and some of the loopholes.

There are a number of other considerations which influenced the design of Euclid:

It is based on current knowledge of programming languages and compilers; concepts which are not fairly well understood, and features whose implementation is unclear, have been omitted.

Although program portability is not a major goal of the language design, it is necessary to have compilers which generate code for a number of different machines, including mini-computers.

The object code must be reasonably efficient, and the language must not require a highly optimizing compiler to achieve an acceptable level of efficiency in the object program.

Since the total size of a program is modest, separate compilation is not required (although it is certainly not ruled out).

The required run time support must be minimal, since it presents a serious problem for verification.

## 2. Summary of the language

*"Be sure of it; give me the ocular proof."*  
*Othello* III, iii, 361.

This section contains a summary of Euclid. The information here is intended to be consistent with the remainder of the report, but in case of conflict the body of the report (sections 3-12) governs. Because it is a summary, many details are omitted, and some general statements are made without the qualifications which may be found in the body of the report.

An algorithm or computer program consists of two essential parts, a description of *actions* which are to be performed, and a description of the *data* which are manipulated by these actions. Actions are described by *statements*, and data are described by *type definitions*. A data type essentially defines a set of values and the actions which may be performed on elements of that set.

The data are represented by *values*. A value may be *constant*, or it may be the value of a *variable*. A value occurring in a statement may be represented by a *literal constant*, an identifier which has been declared to be *constant*, an identifier which has been declared as a *variable*, or an *expression* containing values. Every identifier occurring in the program must be introduced by a *declaration*. A constant or variable declaration associates with an identifier a data type, and either a value or a variable.

In general, a *definition* specifies a fixed value, type, or routine, and a *declaration* introduces an identifier and associates some properties with it. A data type may either be directly described in the constant or variable declaration, or it may be referenced by a type identifier, in which case this identifier must be introduced by an explicit *type declaration*.

A *constant declaration* associates an identifier with a value; the association cannot be changed within the scope of the declaration. If the value can be determined at compile-time, the constant is said to be *manifest*; the expression defining a manifest constant must contain only literal constants, other manifest constants, and built-in operations.

An *enumerated type definition* indicates an ordered set of values, i.e., introduces identifiers standing for each value in the set. The *simple* data types are the enumerated types, the subrange types, and the four *standard simple types*: *Boolean*, *integer*, *char* and *StorageUnit*. The *real* type has been omitted. For the first three, there is a way of writing literal constants of that type: True and False for Boolean, numbers for integers, and quotations for characters. Numbers and quotations are syntactically distinct from identifiers. The set of values of type *char* is the character set available in a particular implementation. The type *StorageUnit* has values which occupy the minimum unit in which storage allocation is done; this may of course differ from one implementation to another. Since no operations are defined on *StorageUnit* values, nothing more need be said about them.

A type may also be defined as a *subrange* of a simple type by indicating the smallest and the largest value of the subrange.

*Structured types* are defined by describing the types of their components, and indicating a *structuring method*. The various structuring methods differ in the selection mechanism serving to select the components of a variable of the structured type. In Euclid, there are five basic structuring methods available: array, record, module, set, and collection.

In an *array structure*, all components are of the same type. A component is selected by an array selector, or *computable index*. The index type, which must be simple, is indicated in the array type declaration. It is usually a programmer-defined enumerated type, or a subrange of the type integer. Given a value of the index type, an array selector yields a variable or constant of the component type. Every array structure can therefore be regarded as a mapping of the index type into the component type.

In a *record structure*, the components (called *fields*) are not necessarily of the same type. In order that the type of a selected component be evident from the program text (without executing the program), a record selector is not a computable value, but instead is an identifier uniquely denoting the component to be selected. These field identifiers are declared in the record type definition. Records may include constant as well as variable components; manifest constant components, of course, do not need to be stored in each record instance.

A record type may be specified as consisting of several *variants*. This implies that different record values, although declared to be of the same type, may assume structures which differ in a certain manner. The difference may consist of a different number and different types of components. The variant which is assumed by a record value is indicated by a constant of some simple type which is called the *tag*.

A *module structure* is much like a record, but may include routines and types as components. In this way, the operations which are defined on a data structure can be conveniently packaged with the structure. Module components cannot be accessed outside the module body unless they are explicitly exported. Thus in a properly written program it is evident from the lexical structure how the state of a module can be altered.

A *set structure* defines the set of values which is the powerset of its base type, i.e., the set of all subsets of values of the base type. The base type must be a simple type.

Variables declared in explicit declarations are called *static*. The declaration associates an identifier with the variable, and the identifier is used to refer to the variable. The language guarantees that two identifiers which can legally be used in the same scope cannot refer to the same variable, or to overlapping variables. Thus, an assignment to an identifier cannot change the value of any other identifier accessible in the same scope.

In contrast, variables may be generated by an executable statement. Such a *dynamic* generation yields a *pointer* value (a substitute for an explicit identifier) which subsequently serves to refer to the variable. This pointer may be assigned to other variables, namely variables of type pointer. Each pointer variable may assume values pointing to variables in a single *collection C*, all of whose members are of the same type. It may, however, also assume the value C.nil, which points to no variable. Because pointer variables may also occur as components of structured variables, which are themselves dynamically generated, the use of pointers permits the representation of finite graphs in full generality. Although the language cannot guarantee in general that two pointer variables do not refer to the same variable, it can make this guarantee for two pointers in different collections.

A *zone* can be associated with each collection to provide procedures for allocating and deallocating the storage required by variables in that collection; if the zone is omitted, a standard system zone is used. The program may free a dynamic variable explicitly, in which case the program is responsible for ensuring that there will be no further references to the non-existent variable. Alternatively, the collection may be *reference-counted*, in which case each variable is automatically freed when no pointers to it remain. The main advantage of reference-counted variables, as compared with explicit deallocation, is that the correctness of the deallocation does not have to be verified.

Throughout this report, the word *variable* means a container which can hold a value of a specific type. A variable may or may not be associated with an identifier. A *constant*, by contrast, is simply a value of a specific type. The fundamental difference is that assignment to a variable is possible.

A type declaration may have formal parameters; such a *parameterized* declaration represents a set of types, one of which is specified each time the type is referenced and actual parameters are supplied for the formals.

Two types are the same if their definitions are identical after any type identifiers which are not *opaque* have been replaced by their definitions, and any actual parameters and any identifiers declared outside the type have been replaced by their values. A type identifier is opaque if it is a module type, or is exported from a module.

The most fundamental statement is the *assignment statement*. It specifies that a newly computed value be assigned to a variable (or a component of a variable). The value is obtained by evaluating an *expression*. Expressions consist of variables, constants, sets, operators and functions operating on the denoted quantities and producing new values. Variables, constants, and functions are either declared in the program or are standard entities. Euclid defines a fixed set of operators, each of which can be regarded as describing a mapping from the operand types into the result type. The set of operators is subdivided into groups of:

1. *arithmetic operators* of addition, subtraction, sign inversion, multiplication, division, and computing the remainder (**mod**).
2. *Boolean operators* of negation (**not**), conjunction (**and**), disjunction (**or**) and implication (**->**).
3. *set operators* of union, intersection, set difference, and symmetric difference (**xor**).
4. *relational operators* of equality, inequality, ordering, set membership and set inclusion. The results of relational operations are of type Boolean.

The *procedure statement* causes the execution of the designated procedure (see below).

There are two kinds of escape statements: an *exit statement* is used to terminate a loop, and a *return statement* to terminate a routine. An escape statement may be qualified by a *when clause*, which causes termination only if a Boolean expression is True.

Assignment, procedure, and escape statements are the components or building blocks of *structured statements*, which specify sequential, selective, or repeated execution of their components. Sequential execution of statements is specified by the *compound statement*;

conditional or selective execution by the *if statement* and the *case statement*; and repeated execution by the *loop statement* and the *for statement*. The if statement serves to make the execution of a statement dependent on the value of a Boolean expression, and the case statement allows for the selection among many statements according to the value of a selector. The discriminating case statement provides a safe way of discriminating the current variant of a variant record. The for statement is used when a bound on the number of iterations is known beforehand, and the loop statement is used otherwise.

A *block* can be used to associate declarations with statements. The identifiers thus declared have significance only within the block. Hence, the block is called the *scope* of these identifiers, and they are said to be *local* to the block. Since a block may appear as a statement, scopes may be nested. An if, case, for or loop statement, or a module type declaration, also defines a scope in a similar way.

A block can be named by an identifier, and be referenced through that identifier. The block is then called a *procedure*, and its declaration a *procedure declaration*. However, an identifier which is not local to a given procedure body is accessible in that body only if it is accessible in the immediately enclosing scope, and

- it is *pervasive* in some enclosing scope or
- it is explicitly *imported* into the given procedure body.

A procedure has a fixed number of parameters, each of which is denoted within the procedure by an identifier called the *formal parameter*, which is local to the procedure body. Upon an activation of the procedure statement, an actual quantity has to be indicated for each parameter which can be referenced from within the procedure through the formal parameter. This quantity is called the *actual parameter*. There are two kinds of parameters: constant parameters and variable parameters; routine and type parameters are not allowed. In the first case, the actual parameter is an expression which is evaluated once. The formal parameter represents a local constant whose value is the result of this evaluation. In the case of a variable parameter, the actual parameter is a variable and the formal parameter is *bound* to this variable. Possible indices or pointers are evaluated before execution of the procedure.

*Functions* are declared analogously to procedures; procedures and functions are collectively called *routines*. The main difference lies in the fact that a function yields a result, which may be of any assignable type and must be specified in the function declaration. Functions may therefore be used as constituents of expressions. Variable formal parameters and imported variables are not permitted within function declarations; as a consequence, functions cannot have side effects.

Since Euclid is intended for the writing of programs which are to be verified (either mechanically or by hand), there are a number of explicit interactions between the language and the verifier, in addition to the many aspects of the language which have been motivated by the desire to ease verification. These explicit interactions fall into two main categories:

embedding of assertions in the program: the special symbols *assert*, *invariant*, *pre* and *post* introduce assertions. These may be written as comments which are ignored by the compiler. Presumably they will be used by the verifier, which can take advantage of their relationship to the structure of the program. Alternatively, an assertion may be written as a Boolean expression, which is compiled into a run-time check if the *checked* option has been specified for an enclosing scope.

compiler-generated assertions: in cases where the compiler needs to be able to assume that some condition holds, but is unable to deduce that it does, the compiler may generate an assertion (in a new listing of the program) for the verifier, and then proceed as though confident of its truth. The legality of the program will then depend on the validity of the compiler-generated assertion. Each case in which such an assertion may be generated is spelled out in this report.

### 3. Notation, terminology, and vocabulary

*"The best words in the best order."*  
Coleridge.

The syntax is described in a modification of Backus-Naur form, in which syntactic constructs are denoted by English words or phrases, not enclosed in any special marks. These words also suggest the nature or meaning of the construct, and are used in the accompanying description of semantics. Basic symbols of the language are written in boldface or enclosed in quote marks; e.g., **begin** and ";". Possible repetition of a construct is indicated by enclosing the construct within metabrackets { and }. Possible omission of a construct is indicated by enclosing the construct within metabrackets [ and ]. The word **empty** denotes the null sequence of symbols.

The grammar defining the syntax of Euclid is distributed throughout this report; for convenient reference, it has also been collected in Appendix A.

#### 3.1 Vocabulary

The primitive vocabulary of Euclid consists of basic symbols classified into letters, digits, and special symbols. Note that this vocabulary is *not* the character set. The character set is implementation dependent, and each implementation must define, in its character set, distinct representations for all the basic symbols. Suggestions for doing this in some common cases may be found in section 13.

Each implementation must specify a single *break character* which can be used within an identifier. Two identifiers are *similar* if they are composed of the same sequence of characters, except for changes from upper to lower case letters or vice versa, and for the presence or absence of break characters. The intended use of the break character is to visually separate an identifier into its component parts. In an implementation which can print upper and lower case letters, a transition from lower to upper case can also be used for this separation. It is recommended that this convention be used when possible, in preference to the explicit break character, for implementations which have lower case letters; obviously it cannot be used if the entire identifier is upper case, for example. Thus, an identifier might be represented as

- |            |   |
|------------|---|
| alphaBeta  | using 96-character ASCII, with capitalization as the break.     |
| ALPHA_BETA | using the IBM PL/I character set, with _ as the break.          |
| ALPHA\BETA | using the Model 33 Teletype character set, with \ as the break. |

All of these identifiers would be similar to the identifier ALPHABETA. With these conventions, it is possible to convert from one representation to another in a reasonable way (see 13.).

Each time an identifier is used, it must be written in exactly the same way (i.e., with the same capitalization and use of break characters) as it was written when it was declared. However, another identifier which is similar according to the above rules may not be declared in any scope in which the first identifier is accessible (see 7.3).

The following capitalization convention is generally used in this report: type and routine identifiers begin with a capital letter (except for certain standard types); other identifiers begin with a small letter. This convention is not part of the definition of Euclid, however.

```

letter ::= "A" | "B" | "C" | "D" | "E" | "F" | "G" | "H" | "I" | "J" | "K" | "L" |
           "M" | "N" | "O" | "P" | "Q" | "R" | "S" | "T" | "U" | "V" | "W" | "X" | "Y" |
           "Z" | "a" | "b" | "c" | "d" | "e" | "f" | "g" | "h" | "i" | "j" | "k" | "l" | "m" | "n" |
           "o" | "p" | "q" | "r" | "s" | "t" | "u" | "v" | "w" | "x" | "y" | "z"

octalDigit ::= "0" | "1" | "2" | "3" | "4" | "5" | "6" | "7"

digit ::= octalDigit | "8" | "9"

hexDigit ::= digit | "A" | "B" | "C" | "D" | "E" | "F"

breakChar ::= <some implementation-dependent character not a letter or digit>

specialSymbol ::= "+"
                  | "-"
                  | "*"
                  | "="
                  | "<"
                  | ">"
                  | "<="
                  | ">="
                  | "->"
                  | "("
                  | ")"
                  | "{"
                  | "}"
                  | ":="
                  | "."
                  | ","
                  | ";"
                  | ","
                  | "^"
                  | "=>"
                  | "<<="
                  | "$"
                  | "#"
                  | wordSymbol

wordSymbol ::=
abstraction | aligned | all | and | any | array | assert | at | begin | bind | bits |
bound | case | checked | code | collection | const | counted | decreasing |
dependent | discriminating | div | else | elseif | end | exit | exports | finally |
for | forward | from | function | if | imports | in | include | initially | inline |
invariant | loop | machine | mod | module | net | of | on | or | otherwise |
packed | parameter | pervasive | post | pre | procedure | readonly | record |
return | returns | set | then | to | type | unknown | var | when | with | xor

```

### The construct

"{" any sequence of symbols not containing "}"> "}"

may be inserted between any two identifiers, literal constants (see 4.), or special symbols. It is called a *comment*, and may be removed from the program text without altering its meaning. The symbols "{" and "}" do not occur otherwise in the language.

Any verification system which accepts Euclid programs as input may define a convention for distinguishing comments which have special meaning for the verifier. One reasonable convention is that every comment in which a certain character appears as the first character after the { is intended for the verifier.

The word *routine* is used as a synonym for the phrase "procedure or function."

### 3.2 Legality assertions

Throughout this report, various restrictions will be placed on *legal* Euclid programs. Many of these restrictions cannot be checked syntactically, and in some cases they involve dynamic conditions that are difficult (or impossible) to check statically. Nevertheless, programs that violate them are not considered to be meaningful Euclid programs. It is the responsibility of the compiler to verify as many of these properties as it can, and to produce Boolean expressions called *legality assertions* for those it cannot. Thus, any program whose legality assertions can all be verified is a legal Euclid program, with well-defined semantics. Note that legality assertions are produced only for conditions specified in this report.

If **checked** is specified for a scope and not overridden by an inner **not checked** (see 6.2.3 and 9.2.1), all legality assertions in the block, and all programmer-supplied assertions which are Boolean expressions, are compiled into run-time checks, as an aid in detecting illegal programs, even before the verification process is complete.

### 3.3 Lexical structure

The text of a program is built up out of declarations and statements, collectively called *units*, according to the syntax specified below. In general units are separated by semicolons. The syntax is constructed in such a way that a unit may *always* be legally followed by a semicolon. In order to make it unnecessary to write semicolons between units which appear on separate lines, a semicolon is automatically inserted at the end of a line whenever the last token of the line could be the end of a unit, namely one of:

identifier, literal constant, ), ↑, exit, return, forward, or end possibly followed by  
if, loop, case, record, or module,

and the first token of the next line could be the beginning of a unit, namely one of:

identifier, literal constant, abstraction, assert, begin, bind, case, const, exit,  
finally, for, function, if, initially, inline, invariant, loop, machine, pervasive,  
procedure, return, type, var or with.

Commas are used as separators in enumerated types, case label lists, element lists, and parameter lists, and within declarations in identifier lists, bind lists, and import/export lists.

There are several kinds of brackets which are used to group declarations and statements for various purposes. The following list gives the unique closing bracket for each opening bracket.

<b>if</b>	<b>end if</b>
<b>loop</b>	<b>end loop</b>
<b>case</b>	<b>end case</b>
<b>=&gt;</b>	<b>end caseLabel</b>
<b>begin</b>	<b>end</b> , or <b>end routineIdentifier</b> whenever the block is the body of a routine
<b>code</b>	<b>end routineIdentifier</b> .
<b>record</b>	<b>end record</b> , or <b>end typeIdentifier</b> whenever the record definition is the declaration of a type identifier.
<b>module</b>	<b>end module</b> , or <b>end typeIdentifier</b> whenever the module definition is the declaration of a type identifier.

#### 4. Identifiers, numbers and strings

*"And twenty more such names as these  
Which never were nor no man ever saw."*

*The Taming of the Shrew, Induction, ii, 95.*

Identifiers serve to denote constants, variables, types, and routines. Their association must be unique within their scope of validity, i.e., within the scope in which they are declared (see 6, 7.3).

```
identifier ::= letter { letterOrDigit }
letterOrDigit ::= letter | digit | breakChar
```

The usual decimal notation is used for numbers, which are the literal constants of the data type integer (see 6.1.2.). Numbers may also be written in octal or hexadecimal notation. Note that unsigned numbers are always positive; a negative manifest constant can be written as an expression, e.g., -14.

```
unsignedNumber ::= digit { digit } |
                  octalDigit { octalDigit } "#8" |
                  digit { hexDigit } "#16"
```

Examples:

1 100 717#8 0CAD1#16 123#16

Sequences of characters enclosed by quote marks are called *literal string constants*. They are the literal constants of the standard type string (see 6.2.2). A character code, whether or not it is in the printing character set, can also be represented in a literal string constant as follows:

\$ddd, where each d stands for a decimal digit, represents the character code with the decimal representation ddd. Note: char.Ord(\$\$ddd) = ddd (see 6.1.2).

For convenience, \$S, \$T, \$N, \$\$, \$' represent space, tab, newline, \$, and ' respectively. The \$ddd construction can be used only in a machine-dependent module (see 6.2.3).

```
literalString ::= " " { extendedCharacter } " "
extendedCharacter ::= character | "$" extension
extension ::= digit digit digit | "S" | "T" | "N" | "$" | " "
```

Examples:

'	'A'	'.'	'\$'	'Here comes a null: \$000 and there it went'
'Euclid'	'THIS IS A STRING'			'This\$Sis\$Sa\$String'

A single character preceded by a dollar sign is a literal constant of the standard type char (see 6.1.2). The \$ convention may also be used in these constants.

```
literalChar ::= "$" extendedCharacter
```

Examples:

\$a \$\$S {space character} \$\$000 {the NUL character} \$" \$\$\$

## 5. Manifest constants

*"One here will constant be,  
Come wind, come weather."  
Pilgrim's Progress*

A manifest constant is a literal constant or an expression which can be used in place of a literal constant. The value of a manifest constant can be computed in a straightforward way at compile time. Thus, a manifest constant expression may not involve any functions, except the standard ones defined in this report. A general constant, by contrast, has a value which is fixed during the lifetime of the scope in which it is defined, but may be computed in an arbitrary way at the beginning of that lifetime.

```
literalConstant ::= unsignedNumber | literalString | literalChar | enumeratedValueId  
manifestConstant ::= literalConstant | manifestConstantExpression  
manifestConstantExpression ::= expression
```

Examples:

-100      \$a      'Euclid'      *red*      *3\*Color.Ord(Color.last)*

## 6. Data types

*"What is written without effort is in general read without pleasure."*

Johnson

A data type determines the set of values which variables and constants of that type may assume, and the set of basic operations that may be performed on them. A type declaration associates an identifier with the type. The type identifier is considered to denote the same type as its definition, unless it is declared as a module type (see 6.2.3) or is exported from a module, in which case the identifier denotes a different type; type equivalence is discussed in detail in 6.4. Parameterized types are introduced in 6.3.

A type declaration introduces a new scope in which the formal parameters of the type, if any, are declared (see 6.3). If the type definition is a module type, the definition is a second, closed scope (see 7.3), and identifiers declared outside it are inaccessible unless imported. If the type definition is not a module type, however, its scope is the open scope of the declaration (or possibly a second, open scope for a record definition), and importing is not necessary (or possible).

An identifier must be *declared* before it is used. When there are mutually recursive routines or types, however, it is impossible to give the *definition* of every identifier before its use. In this situation, a definition of **forward** may be given instead, and later another declaration, of the form **type**  $T=...$  (or **procedure**  $P=...$ , or **function**  $F=...$ ) must appear to provide the true definition. Between its forward and true definitions, or within its own definition, a type may only be used as the object type of a collection, or to declare a formal parameter. If an identifier declared with **forward** has parameters, these must appear in the forward definition and must *not* be repeated in the true definition.

A type declaration may not contain variable identifiers which are free, i.e., declared outside the type declaration, except that a module definition may explicitly import variables. As a consequence, an unparameterized type identifier denotes the same type throughout the scope in which it is declared, and the type denoted by a parameterized type identifier depends only on the values of the actual parameters. Note, however, that the same type identifier may denote different types in different scopes, e.g., in different instantiations of a routine or a module.

All types (except integer) automatically acquire components when they are declared. For example, an array type  $T$  has the component  $T.\text{IndexType}$  (see 6.2.1). Any component of a type is automatically also a component of every constant or variable of that type. Thus if  $e$  is a constant or variable of type  $T$ ,  $e.\text{IndexType}$  is the same as  $T.\text{IndexType}$ .

This report specifies the *standard* representations, in terms of bits, for the values of certain types. These specifications are given so that machine-dependent records and machine-code procedures can be sensibly defined, and so that the effect of an explicit type conversion can be predicted. The following contexts are defined as *sensitive*:

- a variable component of a machine-dependent record (see 6.2.4)
- a variable declared at a fixed address (see 7.)
- an actual parameter or result of a machine-code routine (see 10.)

the actual parameter or result of an explicit type conversion (see 6.5)

A type may not appear in a sensitive context unless its standard representation is specified, either in this report, or explicitly by the implementation. Except in these sensitive contexts, there is no way for a Euclid program to determine the standard representation of any value, and an implementation is therefore free to use other representations, provided that it converts each value to the standard representation when it appears in a sensitive context.

```
type ::= simpleType | structuredType | pointerType | parameterizedTypeReference
typeDeclaration ::= type typelIdentifier formalParameterList =
                  preAssertion typeDefinition
typelIdentifier ::= identifier
typeDefinition ::= type | forward
```

There are two components implicitly declared for each type other than integer:

<i>T.size</i>	the result, of type integer, is the number of StorageUnits (see 6.1.2) required for the representation of a variable of type <i>T</i> .
<i>T.alignment</i>	the result, of type integer, is the required alignment of variables of type <i>T</i> , in StorageUnits. Thus, if <i>p : pType</i> is a pointer to such a variable, then $(\text{AddressType} \ll= \text{pType}(p)) \mod \text{pType.alignment} = 0$ .

There is a component implicitly declared for each variable or constant:

<i>x.itsType</i>	the type of <i>x</i>
------------------	----------------------

### 6.1. Simple types

There are no type variables in Euclid. However, a type may be a component of a module (see 6.2.3), and hence may be referenced by a field designator (see 7.2.2), as well as by an identifier.

```
simpleType ::= enumeratedType | standardSimpleType | subrangeType |
              derivedSimpleType
derivedSimpleType ::= [ containingVariable ":" ] simpleTypelIdentifier
simpleTypelIdentifier ::= identifier
```

#### 6.1.1. Enumerated types

An enumerated type defines an ordered set of values by enumeration of the identifiers which denote these values. There must be at least two such identifiers. The identifiers are declared as constants in the current scope. If the current scope is a type declaration of type *T*, for which the enumerated type is the definition, however, the identifiers are declared in the enclosing scope instead, i.e., the scope in which *T* is declared. In any case, the identifiers may not be used for any other purpose in the scope in which they are declared.

The standard representation of the *i*th identifier (counting from 0) in the enumeration is the same as the representation of the unsigned integer *i*. Thus, if *T* is an enumerated type,

*T.first* is represented exactly like the integer 0.

```
enumeratedType ::= "(" enumeratedValueId { "," enumeratedValueId } ")"
enumeratedValueId ::= identifier
```

Examples:

```
type Color = (red, green, blue, orange, yellow, purple)
type Suit = (club, diamond, heart, spade)
type Day = (Monday, Tuesday, Wednesday, Thursday, Friday, Saturday, Sunday)
type SexType = (female, male)
type Classification = (confidential, secret, topSecret)
type Device = (disk, display, keyboard, printer, tape)
```

Components implicitly declared for each enumerated and subrange (see 6.1.3) type *T* are:

<i>T.first</i>	the first value (in the enumeration)
<i>T.last</i>	the last value (in the enumeration)
<i>T.Succ(x)</i>	the value succeeding <i>x</i> (in the enumeration). <i>T.Succ(T.last)</i> is undefined if <i>T</i> is an enumerated type, or <i>T</i> is a subrange of an enumerated type <i>U</i> and <i>T.last=U.last</i> .
<i>T.Pred(x)</i>	the value preceding <i>x</i> (in the enumeration). <i>T.Pred(T.first)</i> is undefined if <i>T</i> is an enumerated type, or <i>T</i> is a subrange of an enumerated type <i>U</i> and <i>T.first=U.last</i> .
<i>T.Ord(x)</i>	an <i>unsignedInt</i> which is the ordinal number of the value <i>x</i> in the enumeration of <i>T</i> . Thus, <i>T.Ord(T.first)=0</i> .

For instance, *Suit.last* is *spade*, and *Day.first* is *Monday*.

### 6.1.2. Standard simple types

The following types are standard in Euclid, and are pervasive throughout all programs (see 7.3):

**integer** Its values are the positive and negative integers, in the mathematical sense. It is not possible to declare a variable to be of type **integer**. Instead, variables can be declared to be of some suitable subrange type. Constants of type **integer** may be declared, however, and numbers are literal constants of type **integer**.

**signedInt,**  
**unsignedInt** Every implementation has two standard types, *signedInt* and *unsignedInt*; they are ordinary subranges of **integer** which are pre-defined for convenience. These are implementation-defined; the intention is that they should be large subranges of **integer** type which can be handled efficiently by the machine, and which contain:

for *signedInt*, equal numbers of positive and negative numbers,  
 or perhaps one more negative number.

for *unsignedInt*, 0 and no negative numbers.

An operation is called *well-behaved* if its operands are in the range signedInt, or unsignedInt, and it yields an integer result in the same range. An implementation must support the evaluation of *any* expression in which all the operations are well-behaved (see 8.1). An implementation may also support the evaluation of expressions involving larger integers (e.g., double-precision integers), but this is not required. It is recommended, however, that on machines which have  $\text{unsignedInt}=0..2^{16}-1$ , at least double-precision integers should be supported.

If  $T$  is defined by type  $T = m .. n$ , for any manifest constants  $m, n \geq 0$ , and  $i$  is a value of type  $T$ , the standard representation of  $i$  is the ordinary binary representation of the integer  $i$ , filled out on the left with any number of extra zeros. The standard representation of a signed integer must be defined by the implementation, but is not defined in this report.

There are two standard functions defined on any subrange of integer:

Abs( $x$ ) returns an integer which is the absolute value of  $x$ .

Odd( $x$ ) returns a Boolean which is True if and only if  $x$  is odd.

Boolean Its values are the truth values denoted by the identifiers False and True. It is defined by type Boolean = (False, True).

char It is an enumerated type whose values are a set of characters determined by the implementation. They are denoted by the characters themselves preceded by a dollar sign (see 4.).

There is a standard function  $\text{Chr}(x: 0..char.\text{Ord}(\text{char.last}))$  with the property that  $\text{char.\text{Ord}}(\text{Chr}(x))=x$ .

Warning: the ordering of the values of type char is implementation dependent. Use of this ordering in comparisons of chars, subranges of chars, or the Chr and char.Ord functions, will in general result in non-portable programs. Unlike most other machine-dependent features of Euclid, this one is not restricted to machine-dependent modules.

StorageUnit This is the basic unit for storage allocation (see 6.3). There are no distinguishable values of this type, and no operations are defined on this type. Thus, a StorageUnit variable simply serves to occupy a known amount of space. The standard representation of a StorageUnit is not defined.

There are two standard components of the type StorageUnit:

sizeInBits, an integer constant which defines the number of bits in a StorageUnit.

Address, a function declared by

function Address ( $A:\text{array } 0..n \text{ of StorageUnit}$ ) returns

AddressType,

which returns the machine address of  $A(0)$ . It may only be used in a machine-dependent module.

**AddressType** This is an unsigned subrange of integer, large enough to hold a full machine address; i.e., a value returned by the function StorageUnit.Address.

### 6.1.3. Subrange types

A type may be defined as a subrange of another simple type by indication of the smallest and the largest value in the subrange. The first constant specifies the lower bound, and the second the upper bound. If type *A* is a subrange of type *B*, and type *B* is a subrange of type *C*, we say that *A* is also a subrange of *C*. The Succ, Pred, first and last components are defined for all subrange types. If *A* is a subrange of *B*, and *a* is of type *A* and *b* is of type *B*, and *a=b*, and the standard representation of *b* is defined, then the standard representation of *a* is the same as the standard representation of *b*.

```
subrangeType ::= constantSum ".." constantSum
constantSum ::= sum
```

Examples:

```
type OneToOneHundred = 1 .. 100
type SymmetricRange = -10 .. 10
type Primary = red .. blue {the values of a Primary are red, green, and blue}
type ScreenPosition = 1 .. 525 {y coordinate for display screen}
```

## 6.2. Structured types

A structured type is characterized by the type(s) of its components and by its structuring method. Moreover, a structured type definition may contain an indication of the preferred data representation: if a definition is prefixed with the symbol **packed**, this is a hint to the compiler that storage should be economized even at the price of some loss in efficiency of access, and even if this may expand the code necessary for accessing components of the structure.

Adding occurrences of **packed** may make a legal program into an illegal one (because of type compatibility (see 6.4) or if a component of the structure has been renamed as an entire variable (see 7.4)), but will not otherwise change the meaning of the program.

```
structuredType ::= [ packed ] unpackedStructuredType | derivedStructuredType
unpackedStructuredType ::= arrayType | recordType | moduleType |
                           mdRecordType | setType | collectionType
derivedStructuredType ::= [containingVariable "."] structuredTypelIdentifier
structuredTypelIdentifier ::= identifier
```

### 6.2.1. Array types

An array type is a structure consisting of a fixed number of components which are all of the same type, called the *component type*. The elements of the array are designated by indices, values belonging to the *index type*. The array type definition specifies both the component type and the index type.

The standard representation of an unpacked array  $A$  of type array  $I$  of  $C$  is defined as follows. Let  $t = C.size + (C.alignment - 1)$ , and  $s = t - (t \bmod C.alignment)$ . Then successive components of  $A$  occupy successive groups of  $s$  StorageUnits, with no unoccupied StorageUnits in between.  $A(I.first)$  occupies the first  $s$  StorageUnits, i.e., the ones with the smallest machine addresses, and  $A(I.last)$  occupies the last  $s$  StorageUnits, i.e., the ones with the largest machine addresses. Each component is aligned in the same way as a variable of type  $C$ . The entire array thus occupies  $\max(0, s * (I.last - I.first + 1))$  StorageUnits. The standard representation of a packed array is not defined.

```
arrayType ::= array indexType of componentType
indexType ::= simpleType
componentType ::= type
```

There are two standard components of an array type  $T$ :

$T.IndexType$	the index type
$T.ComponentType$	the component type

Like other components of types, they are also components of any variable or constant of the type (see 6.). Thus if  $a$  is a variable of type  $T$ , then  $a.IndexType$  is the same as  $T.IndexType$ , and likewise for  $ComponentType$ .

Examples:

```
type Array0 = array 1 .. 100 of signedInt
type Array1 = array -10 .. 10 of 0 .. 99
type Array2 = array Boolean of Color
type NameTable = array OneToOneHundred of string(50)
```

#### 6.2.2. Record types

A record type is a structure consisting of a fixed number of components, possibly of different types. The record type definition specifies for each component, called a *field*, its type and an identifier which denotes it. The scope of these *field identifiers* is the record definition itself. They are also accessible within a field designator (cf. 7.2) referring to a record variable or constant of this type. Record components may be constants or variables. Components other than variables are accessible within a field designator referring to the type itself, as well as in a designator referring to a variable.

For the syntax of constant and variable declarations, see 7. If the record type appears as the definition of a type identifier, it must end with the clause `end identifier`; otherwise it must end with `end record`.

The size of a record containing an unpacked array is equal to some constant value, independent of the array size, plus the size of the array. The standard representation of a record is not defined.

```
recordType ::= record fieldList endRecord
endRecord ::= end record | end identifier
fieldList ::= [ recordDeclaration [";"] ] [ variantPart ] [ ";" ]
recordDeclaration ::= pervasive recordDeclarationPart
                     { "," pervasive recordDeclarationPart }
recordDeclarationPart ::= constantDeclaration | variableDeclaration
pervasive ::= pervasive | empty
```

A record type may have several *variants*. In this case a constant of some simple type must be used as a selector in a case construction which enumerates the possible variants. This constant is called the *tag*, and its value indicates which variant is assumed by the record variable at a given time. Each variant structure is identified by a case label which is a set of manifest constants of the type of the tag. Usually the tag will be a formal parameter of the type declaration in which the case appears (see 6.3). When a variable of the record type is declared, however, the tag must be a manifest constant, or *any*.

The case label lists must be disjoint. Furthermore, the union of the lists must exhaust the enumerated type of the tag, unless there is an *otherwise* variant, in which case all the tag values not mentioned explicitly are lumped under that variant. The case label following the *end* of the variant must be one of the labels specified by the case label list.

```

variantPart ::= case tag of variant { ";" variant } [ otherwiseVariant ] [ ";" ] end case
variant ::= caseLabelList ">" fieldList end caseLabel | empty
caseLabelList ::= caseLabel { ";" caseLabel }
caseLabel ::= manifestConstant | subrangeType
tag ::= constant
otherwiseVariant ::= otherwise ">" fieldList

```

Examples:

```

type Date = record
  var day: 1 .. 31
  var month: (Jan, Feb, Mar, Apr, May, Jun, Jul, Aug, Sep, Oct, Nov, Dec)
  var year: 1900 .. 2100
end Date

type stream (dev: Device) = record
  case dev of
    display =>
      var first, last: DisplayControlBlock {not defined in this report}
      var height: ScreenPosition := ScreenPosition.first
      var nLines: 0 .. (ScreenPosition.last)/8
      end display
    tape, disk =>
      var file: FileHandle {not defined in this report}
      var position: unsignedInt := 0
      var buffer: array 0 .. 255 of char
      end tape
    keyboard =>
      var buffer: array 0 .. 20 of char
      var bufFirst, bufLast: buffer.IndexType := buffer.IndexType.first
      end keyboard
    otherwise => {null fieldList}
  end case
end stream

```

There are three pervasive standard types having to do with strings, declared as follows.

```
type StringIndex = 1 .. stringMaxLength
type StringLength = 0 .. stringMaxLength
type string(maxLength: StringIndex) = record
    var length: 0 .. maxLength := 0;
    var text: packed array 1 .. maxLength of char
end string
```

Literal string constants are of type string, with *length* equal to the number of characters. The *maxLength* of a literal string constant is chosen to make its type suitable for the context in which it appears; it must not be less than the *length*, however. Routines can readily be defined to extract substrings, do pattern matching, or perform any other desired operations on strings (see 10. and 11. for examples). Furthermore, these routines might be machine-coded for efficiency. The value of the pervasive manifest constant stringMaxLength is implementation-defined.

### 6.2.3 Module types

A module type is a generalization of a record type. Module components may be declared as constants, variables, routines, or types. These declarations have the same form and the same meaning as the declarations in a block. Thus, a module serves as a package for a collection of related objects. A module type is always opaque; i.e., it is not the same as any other type (see 6.4). Thus, two different module definitions always define different types, even if the definitions are textually identical.

Identifiers declared in a module are not known outside unless they are *exported* explicitly, so the packaging supplied by the module also provides protection against improper use of components which are intended to be known only within the module definition. An exported identifier *x* is accessible (but only within a suitable field designator) in any scope in which the module type is accessible. A constant identifier is always exported as a constant; this may be specified by a binding condition of **const**, or the binding condition may be omitted. A variable identifier may be exported as a variable, using the binding condition **var**, or as a readonly variable, using the binding condition **readonly** or omitting the binding condition (see 7). A variable may not be exported as a constant. No two variables in the union of the import and the export lists of a module may overlap (see 7.4).

A constant or variable identifier may not be exported unless its type is exported, or is accessible in the scope *S* enclosing the module definition; the *itsType* component of an exported constant or variable is automatically exported. Similarly, a routine identifier may not be exported unless the types of its parameters and results are exported or accessible in *S*.

When a type *T* is exported from a module *M*, it is always opaque outside its defining module; i.e., it is not the same as any other type (see 6.4). Thus all operations on values of type *T*, other than possibly assignment and equality tests, must be performed by routines defined in *M*. The export item for a type may specify, in an appended **with** clause, that it is to be exported with assignment, equality or both; an operation not specified is not exported. If assignment is not exported, then *T* is not *assignable*; i.e., outside *M* constants or constant parameters of type *T* cannot be declared, and variables of type *T* cannot appear on the left side of an assignment statement. Furthermore, *T*'s field identifiers (including standard ones, like size) are not accessible outside *M*, unless the **with** clause specifies that they should be exported. If *T* is an array type, subscripting is exported if and only if the *IndexType*

component is exported. If  $T$  is an enumerated type, its enumerated value identifiers are not exported unless they are mentioned explicitly in  $T$ 's with clause; subrangeType is permitted in an exportItem to facilitate this. Only an exported type identifier may have a with clause.

Values of the module type itself may not be assigned or compared for equality unless := or =, respectively, appear in the export list. Furthermore, := and = may not appear in the export list if the module imports any variables.

The identifiers which may be exported from a module are those which are accessible in the scope between the end of the module's declarations and the end of the module; loosely, these are just the identifiers declared at the outermost level in the module.

A module is a closed scope; i.e., identifiers declared outside the module are not known inside unless they are known in the immediately enclosing scope, and either are pervasive or are explicitly imported into the module (by the imports clause in the module definition, or because they appear in the formal parameter list of the module declaration). Importing is discussed in detail in 7.3.

The optional identifier following **module** in the type definition may be used within the definition to name the entire value, i.e., for self-referencing.

A module type may be prefixed with the symbols **machine dependent**, which simply means that it may contain other machine-dependent module and record declarations, fixed addresses in variable declarations (see 7.), extended characters of the form \$ddd (see 4.), type converters involving types with implementation-dependent representations (see 6.5), uses of StorageUnit.Address (see 6.1.2), and machine-code procedure declarations (see 10.); a module which is not machine-dependent may not contain any of these things. Thus it is possible to tell from the heading of a module type whether it contains any machine dependencies or not. Note that machine-dependent identifiers exported from a machine-dependent module, as well as the machine-dependent module type itself, may be used in other modules which are not machine-dependent. Since exported types can only be manipulated by exported routines, the routines serve to encapsulate the machine-dependencies.

The standard representation of a module is not defined.

```

moduleType ::= [ machine dependent ] module [ identifier ]
              importClause exportClause moduleBody endModule

endModule ::= end module | end identifier

importClause ::= imports "(" importItem { "," importItem } ")" | empty

importItem ::= pervasive bindingCondition identifier | typeConverter

exportClause ::= exports exportList [ ";" ] | empty

exportList ::= "(" exportItem { "," exportItem } ")"

exportItem ::= bindingCondition identifier [ with exportList ] | ":" | "=" |
              subrangeType

bindingCondition ::= const | readonly | var | empty

```

A module may include an *initial* action which is executed whenever a new variable of the module type is created, and a *final* action which is executed whenever such a variable is

destroyed. Note that if several module variables are declared, as in the program fragment

```
begin x:M1; y:M2; z:M1; ... end
```

the order of creation is *x*, *y*, *z*, and the order of destruction is *z*, *y*, *x*. This follows from the fact that the three declarations start three nested scopes, all of which end at the end (see 7.3).

A module may also specify an *invariant* which is supposed to be true during the lifetime of the module variable (i.e., after the execution of the initial action and before the execution of the final action), except perhaps when one of the procedures of the module has been called and has not yet returned. Like other assertions, this one may be empty or a Boolean expression. In the former case the content of the assertion is supplied in a comment. This comment is of course ignored by the compiler, but presumably is interpreted by the verifier. In the latter case the assertion must be a legal Boolean expression, but it generates code only if the checked option is enabled for the enclosing scope.

The abstraction function, necessary for one approach to the verification of modules [Hoare 1972, London et al. 1977], maps the variables inside the module into a value of the module type. The need for this mapping in verification arises because a variable of the module type is represented inside the module by different variables. The body of the abstraction function may contain constructs outside Euclid in the same way that assertions may, i.e., within comments. The abstraction function is not callable from a Euclid program.

```
moduleBody ::= checkedClause declaration [ ";" ] initialAction invariant finalAction
checkedClause ::= checked | not checked | empty
declaration ::= empty | pervasive declarationPart { ";" pervasive declarationPart }
declarationPart ::= constantDeclaration | variableDeclaration | typeDeclaration |
procedureDeclaration | functionDeclaration
initialAction ::= initially routineDefinition ";" | empty
invariant ::= [abstraction functionDeclaration] invariant assertion ";" | empty
assertion ::= expression | empty
finalAction ::= finally routineDefinition ";" | empty
```

The following example outlines how one might package floating-point numbers and operations on them in a module. Examples of complete modules may be found in section 12 and Appendix B.

```
var Real: machine dependent module
    exports (Add, Subtract, Times, Div, Greater, const zero, number,
            Value with (:=, =, sign, exponent, mantissa))
    type Exp = -80#16 .. 7F#16; type Mant = 0 .. 0FFFFFF#16
    type Value = machine dependent record
        var sign (at 0 bits 0 .. 0): 0 .. 1 := 0
        var exponent (at 0 bits 1 .. 7): Exp := 0
        var mantissa (at 0 bits 8 .. 31): Mant := 0
    end Value
    const zero: Value := (0,0,0)
    inline function number (m: signedInt, ex: Exp) returns num: Value =
```

```

imports (Mant)
begin
  if m < 0 then num.sign := 0 else num.sign := 1 end if
  num.mantissa := Abs(m); num.exponent := ex
end number

function Add (const l, r: Value) returns sum: Value =
  code ... end Add

inline function Greater (const l, r: Value) returns Boolean =
  imports (signedInt<<=Value)
  begin {use type converters to compare l & r as signedInts}
  return True when (signedInt<<=Value(l)) > (signedInt<<=Value (r))
  return False
end Greater

...
end Real

```

#### 6.2.4 Machine-dependent records

A machine-dependent record type is a restricted kind of record type which allows the programmer to specify the exact position and size of each variable field. The position is specified in StorageUnits, where the first StorageUnit of the record is numbered 0, and then in bits, where the first bit of the specified StorageUnit is numbered 0, and the bit numbering continues to successive StorageUnits in the obvious way. The ordering of bits in a StorageUnit is implementation-defined. If the bits clause is omitted, the field occupies an integral number of StorageUnits, and its size is computed from the size of its type; the value is right-justified in the field. The compiler's responsibility is to check that fields do not overlap and that each field is at least large enough to hold values of its type. The size of a value of machine-dependent record type is determined by the largest position specified by the declaration, where the value of the at clause (in StorageUnits) is added to the ending value of the bits clause (in bits). An implementation may place restrictions on how fields overlap natural storage boundaries. The index type specifying bits must be a subrange of integer, and must be manifest except possibly for the last component of the record.

A machine-dependent record may have constant components like an ordinary record. It may not have any parameters. All its variable components must have position specifications, and they cannot be exported or passed as variable parameters. Furthermore, they must all have types whose standard representation is specified. Note that the standard representation of a machine-dependent record is specified, but the standard representation of an ordinary record is not.

An alignment clause, **aligned mod *a***, in a machine-dependent record declaration forces a value of the record type to be allocated so that the machine address of its first StorageUnit is 0 mod *a*, *a* must be a power of 2.

The module in which a machine-dependent record type appears must be a machine-dependent module.

```

mdRecordType ::= machine dependent record [ alignmentClause ]
    mdDeclarationPart { ";" mdDeclarationPart } endRecord

mdDeclarationPart ::= constantDeclaration |
    var identifier "(" at manifestConstant [ bits simpleType ] ")"
    ":" typeDefinition [ initialization ]

alignmentClause ::= aligned mod manifestConstant

```

### Examples

```

type InterruptWord = machine dependent record aligned mod 8
    var device (at 0 bits 0 .. 2): DeviceNumber;
    var channel (at 0 bits 3 .. 5): 0 .. 7;
    var stopCode (at 0 bits 6 .. 7): (finishedOk, errorStop, powerOff);
    var command (at 1 bits 0 .. wordSize): ChannelCommand
end InterruptWord

```

### 6.2.5. Set types

A set type defines the range of values which is the powerset of its *base type*. Base types must be simple types. Operators applicable to all set types are:

- + union
- set difference: *i* appears in *a-b* if and only if it appears in *a* and not in *b*.
- xor symmetric difference: *i* appears in *a xor b* if and only if it appears in exactly one of *a* and *b*.
- \*
- in membership
- <=, >= set inclusion

Sets can be built up from values of the base type as described in section 8. The standard representation of a set *S* : set of *B* is defined if *B* is a manifest type and the standard representation of values of *B* is defined. It is a sequence of *n* significant bits, where *n*=(*B.last-B.first+1*), preceded by any number of insignificant zero bits. If the significant bits are numbered 0, 1, ..., *n*-1, then bit *i* is one if and only if *x* is in *S* and *B.Ord(x)=i*.

```

setType ::= set of baseType
baseType ::= simpleType

```

There is one standard component of a set type *T*:

*T.BaseType* the base type

Examples:

```

type Hue = set of Color
type SubtractivePrimaries = set of red .. green
type SymSet = set of -5 .. +5
type EntriesInUse = set of Array1.IndexType

```

### 6.2.6. Pointer and collection types

A variable which is declared in a program (see 7.) is referred to by its identifier. The variable exists during the entire lifetime of the scope to which it is local, and such a variable is therefore called *static*. In contrast, variables may also be generated dynamically, i.e., without much correlation to the structure of the program. These *dynamic* variables are generated by the standard procedure component *New* described below; since they do not occur in an explicit variable declaration, they cannot be referred to by an identifier. Instead, they may be referred to by a *pointer* value which is provided by *New* when the dynamic variable is generated. A pointer type thus consists of an unbounded set of values pointing to elements of the same type. No operations are defined on pointers except the test for equality, the pointer following operator  $\uparrow$  which yields the variable referred to by the pointer, and the standard function component, *Index*, which converts a pointer into an integer.

The standard representation of a pointer is the same as the standard representation of an *AddressType*.

A dynamic variable must be an element of a *collection*. A collection is not a type: it is a variable which behaves very much like an array variable. Just as an element of an array variable *A* can be referenced by subscripting *A* with an index whose type is the index type of *A* (*A.IndexType*), so an element of a collection *C* can be referenced by subscripting *C* with a pointer whose type is the pointer type of *C* ( $\uparrow C$ ). There are two differences:

No two collections have the same pointer type. Hence the pointer alone is sufficient to specify the collection, and we allow *p* as shorthand for *C(p)*, where *p* is of type  $\uparrow C$ .

There are no operations which produce pointer results, except the standard procedure *C.New* which creates a new variable (or an explicit type conversion). Hence the storage allocation strategy for collections can be quite different from the strategy for arrays.

The reason for having collections is that two pointers to different collections are guaranteed to point to different variables; two pointers to the same collection are either equal, and point to the same variable, or unequal, and point to non-overlapping variables. Hence collections are a means by which the programmer can express some of his knowledge about the ways in which his program is using pointers. If he prefers not to do this, or has no knowledge about pointers to variables of type *T* which can be expressed in this way, he can simply declare a single collection of *T*s and use it everywhere.

There are no operations on collections. A collection may not be assigned to another collection. In fact, there is nothing to do with a collection except to subscript it, or to pass it as an actual parameter.

Associated with every collection is a *zone* which provides storage for its variables. A zone is a module variable with three special components (and possibly other components):

a variable *storageBlocks* which is a collection of a record type containing a special component (and possibly other components):

*theStorage*, a *StorageUnit*

a procedure *Allocate*(*size*, *alignment*: unsignedInt, var *pointer*:  $\uparrow$ *storageBlocks*)  
 a procedure *Deallocate*(*pointer*:  $\uparrow$ *storageBlocks*, *size*: unsignedInt)

These components must not be exported; they are intended only for use by the standard procedures New and Free. A zone must be a machine-dependent module variable. Note that a collection *C*'s zone must be imported as a variable into any scope in which *C*.New or *C*.Free is called. If *C* is reference-counted, *C*.zone must also be imported as a variable into any scope in which a non-local variable of type  $\uparrow$ *C* is assigned to. Appendix B contains examples of module types which implement zones.

A collection declared without a zone will get a standard zone called SystemZone. This zone is not pervasive (since it is a variable), but must be imported where it is needed.

A collection can be *reference-counted*, in which case a variable in the collection will be freed automatically when no pointers to it remain. The optional manifest constant is an integer which gives the maximum reference count which should be maintained; any variable to which more than this number of pointers ever exists at one time may never be freed. The Free procedure does not exist for a reference-counted collection.

```

collectionType ::= [ counted [ manifestConstant ] ] collection of
                  objectType [ in zone ]
objectType ::= type
zone ::= variable
pointerType ::= " $\uparrow$ " collectionVariable
collectionVariable ::= variable
  
```

There are six standard components of a collection variable *C*:

<i>C.nil</i>	a pointer which points to no variable at all.
<i>C.ObjectType</i>	the object type. If there are any <b>unknowns</b> in the collection definition, <i>C.ObjectType</i> is a parameterized type with formal parameters corresponding to the <b>unknowns</b> , in the same order (see 6.3).
<i>C.zone</i>	the zone (see above).
<i>C.Index</i> ( <i>obj</i> : $\uparrow$ <i>C</i> )	a function which takes a pointer to <i>C</i> and returns an integer. This function has only one defined property: it is one-to-one.
<i>C.New</i> (var <i>p</i> : $\uparrow$ <i>C</i> )	allocates a new variable <i>v</i> of type <i>T</i> in collection <i>C</i> and assigns the pointer to <i>v</i> to the pointer variable <i>p</i> . <i>C.New</i> imports <i>C</i> as a variable. This procedure works by calling <i>Allocate</i> for the pointer's zone with <i>T.size</i> and <i>T.alignment</i> as parameters. It gets back a $\uparrow$ <i>storageBlocks</i> , and uses the <i>theStorage</i> component in this block as the first StorageUnit for the newly created variable. It is up to the verifier of the zone to ensure that a sequence of at least <i>n</i> free StorageUnits begins there if <i>Allocate</i> ( <i>n</i> , <i>i</i> , <i>p</i> ) was called, and that the storage allocated does not overlap with that of any other variable. Any initialization specified by the type of <i>v</i> is performed. If the object type of <i>C</i> is parameterized, and any of the actual parameters are <b>unknown</b> , then specific

values for these parameters must be supplied as additional parameters to New, and in the same order in which they appear in the type's formal parameter list, so that the variable being created will have a definite type.

*C.Free(var p: ↑C)*

frees the variable *v* pointed to by *p* and sets *p* to C.nil. The variable becomes undefined. *C.Free* imports *C* as a variable. Any finalization specified by the type of *v* is performed. Then the *Deallocate* procedure for *C*'s zone is called with a pointer to the *storageBlocks* variable from which *v* was originally allocated by *C.New*, and the size which was given to *C.New*. This procedure is not defined for reference-counted collections.

Note that New and Free are procedures which violate the strict type checking of Euclid. These procedures, explicit type conversions (see 6.5) and machine code routines (see 10), are the only ways of doing so.

Examples:

```
var myStreams: collection of Stream(unknown) in ioZone
type StreamRef = ↑myStreams
var userInput, userOutput, anyStream: StreamRef
...
myStreams.New(userInput, keyboard)      {create & initialize input Stream}
myStreams.New(userOutput, display)       {also an output stream}
myStreams.New(anyStream, any)
var stringStorage: collection of string(unknown)
type StringRef(maxLength: StringIndex) = ↑stringStorage(maxLength)
```

### 6.3 Parameterized types

It is possible to declare a parameterized type by including a formal parameter list (see 10.) in the type declaration:

```
type T(a: signedInt, b: color) = ...
```

Every reference to such a type (i.e., every use of *T* except in an import or export list) must have an actual parameter list which supplies values for all the formal parameters. Thus, a parameterized type is like a template, from which a number of types can be obtained by supplying actual parameters for the formals. The formal parameters of a type must be constant, and of an assignable type; a type may not have a variable formal parameter.

When a parameterized type is referenced in the formal parameter list of a procedure, an actual parameter of the reference can be a previous formal parameter of the procedure (see 10.). Thus, procedures can be written to accept actual parameters whose type is any reference to a parameterized type.

The built-in type constructors **array** *i..j* of *T*, *i..j* (subrange), **case** *c* of ... (variant part of a record type), and  $\uparrow C$  also take parameters. In fact, the first three can take parameters of any simple type, and the last can take any collection. Thus all four are unlike user-defined parameterized types, in which the types of the parameters are specified in the formal parameter list. For subrange, array and case the actual parameters must be constants, but need not be manifest. Thus, textually identical occurrences of one of these constructors do not necessarily produce the same type.

The **case** constructor is normally used in the declaration of a type *T* in which its parameter is in turn declared to be a (necessarily constant) formal parameter of *T*. Note that when *T* is referenced, actuals must be supplied for all its formals, even though some of the formals may be referred to only in a variant which is not selected. Furthermore, the actual parameter supplied for the tag must be a manifest constant, **any** or **unknown**.

Parameters of a type may be referenced like record components; thus after

```
type T(p: color) . . . ; var x: T(red)
```

the expression *x.p=red* is True. Note that the parameters of a module type need not be exported, since they are declared outside the module definition.

When a parameterized type *T* is referenced (e.g., in the declaration of a variable), the actual parameters are substituted for the formals, and an unparameterized type results. In certain cases, however, Euclid makes it possible to defer fixing the value of a parameter. In particular:

If a parameter is the tag of a variant, it may be specified as **any**, so that a variable can be changed from one variant to another during execution, by assigning values of different variants to the variable.

If *T* is referenced as the object type of a collection, one or more parameters may be specified as **unknown**, and fixed only when a variable in that collection is created.

If *T* is the type of a formal parameter of a routine, one or more parameters of *T* may be specified as **parameter**. This is a shorthand which indicates that they are to be passed as additional parameters of the routine.

The first two cases are described in detail below; for the third, see 10.

The special value **any** may be used as an actual parameter of a type reference, provided that the corresponding formal is only used as the tag of a variant. Suppose  $V$  is such a parameterized type, with a formal parameter  $s$ , of enumerated type  $T$ , used as a tag (there might be other formals, but they are omitted in this example). Then  $V(\text{any})$  is a type whose values are the union of the values of  $V(i)$  as  $i$  ranges over all the elements of  $T$ . It differs from any particular  $V(i)$  in two important ways:

If  $x$  is declared to be of type  $V(\text{any})$ , only those components of  $x$  which are outside the case constructor with tag  $s$  can be referenced. A discriminating case statement (see 9.2.2.2) can be used to bind  $x$  to an identifier  $y$  whose type is  $V(i)$ , and then all the components of  $y$  can be referenced in the scope of the discrimination.

The value of the parameter  $x.s$ , and hence the choice of variant, can be changed during execution by assignment to  $x$  (but not, of course, to  $y$  if  $y$  is of type  $V(i)$ ). This is the only case in which any property of a variable which is determined by the parameters of its type can be changed after the variable has been created.

The special value **unknown** may be used as an actual parameter in a type reference, provided the reference appears as the object type of a collection. A variable in the collection can only be created by the standard procedure **New**, however (see 6.2.6), and when **New** is called, actual parameters must be supplied for all the **unknowns** in the object type; note that **any** is a legitimate actual parameter. Hence a type never involves **unknown** except in the object type of a collection. When a pointer to **collection of  $T(\dots, \text{unknown}, \dots)$**  is dereferenced to yield a variable  $v$ , that variable has type  $T(\dots, x, \dots)$ , where  $x$  is the value which was supplied to **New** when  $v$  was created.

As in other cases where the parameters of types are not manifest constants, the compiler may have to generate legality assertions to ensure that the type of a dereferenced pointer has some property demanded by the context in which the dereferenced pointer is used. If the **unknown** parameter is only used as the tag of a variant, a discriminating case statement can be used to bind a referenced variable to an identifier of known type, just as is done with **any**.

Note that all actual parameters in an object type other than **any** and **unknown** are evaluated when the collection is declared, *not* when a variable in the collection is created.

```
parameterizedTypeReference ::= [containingVariable "."] typelIdentifier
                           "(" typeActualParameter
                           { "," typeActualParameter } ")"
typeActualParameter ::= expression | any | unknown | parameter
```

Examples of type definitions:

```
type FamilyMember(sex: SexType) = forward
var members: collection of FamilyMember(unknown)
type FamilyMember = record
  var age: 0 .. 100
  var mother, father, sibling: ↑members
  var oldestChild: ↑members
end FamilyMember
```

```
type Subject = FamilyMember(any)
type Family = ↑members
```

#### 6.4 Type compatibility

This section defines the conditions under which two types are the same, and describes the rules for type compatibility in the language. The basic idea is this: a type identifier is an abbreviation for its definition. After all such abbreviations have been removed, two types are the same if their definitions look the same. However, a module type, or any type exported from a module, is considered to be different from any other type; hence operations on such a type are restricted to procedures defined in the module.

Two types are the *same* if their *expanded definitions* are equal. The expanded definition of a type is obtained by the following algorithm:

Start with the type.

Replace each type identifier by its definition, unless the definition is a module type, or the identifier was exported from a module. During this replacement, substitute any actual parameters for the corresponding formals.

Replace *x.itsType* by the type of *x*. If *x* is a formal parameter, and its type has occurrences of **parameter**, replace them with additional formals as described in 10.

Repeat these replacements until there are no more to be done.

The result is the expanded definition.

Two expanded definitions are equal if,

when all *extended parameters* of types (including array, subrange, case and ↑ constructors) are removed, they are identical sequences of basic symbols;  
each extended parameter in one sequence is equal to the corresponding extended parameter in the other sequence.

The extended parameters of a type are the actual parameters, if any, together with the values of all constant identifiers used free (i.e., not declared) in the type definition.

If the compiler cannot determine whether or not two types are the same (e.g., because their constant parameters are not manifest), and they must be the same for the program to be legal, then the compiler will assume that they are the same, and generate a legality assertion guaranteeing this fact for the verifier to prove.

When a value is assigned to a variable, or a variable is bound to an identifier, the types must be *compatible* according to the following rules:

an operand for any operator other than dot, subscripting, and ↑, must have a type which is not parameterized;

in an assignment, both types must be the same, except that

ranges of variables on the left side may differ from the ranges of the corresponding components on the right side (Note, however, that other parameters of types, such as array bounds, may *not* differ). In a legal Euclid program, each actual value being stored will be within

the range of the corresponding variable. Where the compiler cannot verify the legality of an assignment, it will generate one or more legality assertions concerning the range of the actual value.

occurrences of *any* as an actual parameter in the type of the variable, and not within the object type of a collection, may correspond to occurrences of *any* value in the type of the right side. Thus, a  $T(\text{red})$  may be assigned to a  $T(\text{any})$ , but not the reverse. Furthermore, a pointer to  $T(\text{red})$  may *not* be assigned to a pointer to  $T(\text{any})$ .

In a binding (see 7.4), the type  $T_v$  of the variable must be the same as the type  $T_i$  of the identifier. If the binding is part of a procedure or function call, however, actual parameters in the specification of  $T_i$  may be other formal parameters of the procedure or function (see 10).

The following table summarizes the transitions which are possible:

<u>To (formal or left side)</u>		$T(\text{red})$	$T(\text{any})$
<u>From (actual or right side)</u>			
$T(\text{red})$		bind assign	assign
$T(\text{any})$		discriminate	bind assign

## 6.5 Explicit type conversions

In recognition of the fact that controlled breaches of the type system are sometimes necessary, Euclid provides a mechanism for specifying such breaches. It takes the form of a class of pseudo-functions called type-converters. A type-converter specifies an explicit conversion from one type (the source) to another (the target). The two types must have the same size, and must not be parameterized. The function takes a value of the source type as its single argument, and produces a value of the target type. No code is generated by the function, except perhaps for code supplied by the implementation to bring the representations of the argument and result into the standard form specified in this report.

It is possible to specify **procedure** or **function** as the source type, so that a program can get hold of the starting address for a routine in order to link to it from a machine code body (see 10.)

A type converter is automatically declared in the largest scope in which both the source type and the target type are declared. However, it may not be referenced in this scope, but must be explicitly imported into any inner closed scope which references it.

If either source or target type has an implementation-dependent representation, the type converter can only appear in a machine-dependent module.

```
typeConverter ::= targetType "<<=" sourceType
targetType ::= typelIdentifier
sourceType ::= typelIdentifier | procedure | function
```

Examples: (from Appendix B)

*CellPtr<<=AddressType*  
*SBPtr<<=CellPtr*

## 7. Declarations and denotations of constants and variables

*"Declare, if thou hast understanding."*  
Job 38, 4

A constant is a literal constant, or an identifier declared as a constant, or an expression containing only constants.

constant ::= expression

A constant declaration consists of an identifier denoting the new constant, followed optionally by its type, and then by an expression which defines its value. The defining expression is evaluated, and its value becomes the value of the constant, which can never change thereafter. The type of the constant, if specified, must be assignable, and assignment-compatible with the type of the defining expression (see 6.4).

A structured constant may be used to define a constant of a structured type which is not a module type. The constants within the parentheses are the values of the components of the structured value. For a record, the order is the order in which the components appear in the definition. For an array *a*, the order is *a*(*a*.IndexType.first) to *a*(*a*.IndexType.last). If the structured type contains other structured types as components, their values are in turn represented as nested structured constants.

```
constantDeclaration ::= const idList [ ":" typeDefinition ] ":" expression |  
                      const idList ":" typeDefinition ":" structuredConstant  
idList ::= identifier { "," identifier }  
structuredConstant ::= "(" [ constantItem { "," constantItem } ] ")"  
constantItem ::= constant | structuredConstant
```

A variable declaration consists of a list of identifiers denoting the new variables, followed by their type and optional initialization, or it consists of a binding. The initialization is exactly equivalent to an assignment statement executed immediately after the declaration of which the variable declaration is a part. A **bind** declaration specifies that each of the identifiers in the bindList is to be bound to an already existing variable, rather than to a newly created one (see 7.4). If the variable binding condition is **readonly**, or omitted, then the newly declared identifier cannot be changed within the new scope. In particular, it cannot be assigned to, or passed as a variable parameter, and the same restrictions apply to any variable which is part of it. All the renamings of components of a single entire variable must be accomplished within a single bindList, since otherwise the no-overlap rule (see 7.3) will be violated.

The fixed address, if present, specifies the physical address in memory where the variable is to be allocated. It is the compiler's responsibility to ensure that a variable allocated at a fixed address does not overlap any other variable. A *fixed-address component* is either a variable declared at a fixed address, or a module type containing a fixed-address component. Such a component may only appear as a component of a machine-dependent module type which is not the definition of a type identifier (i.e., is not named). It is a consequence of the no-overlap rule that only one variable of each type with a fixed-address component may be declared.

Note that a variable may not be declared to be of type integer, but only of some subrange type. Constants may be of type integer, however.

```

variableDeclaration ::= var variableDeclarer |
                     bind variableBinding | bind "(" bindList ")"
bindList ::= variableBinding {"," variableBinding}
variableBinding ::= varBindingCondition identifier to variable
varBindingCondition ::= readonly | var | empty
variableDeclarer ::= idList [ fixedAddress ] ":" typeDefinition [ initialization ]
fixedAddress ::= "(" at manifestConstant ")"
initialization ::= "=" expression

```

Examples:

```

const iC, jC := -1 {iC and jC will be integers and have the value -1}
const tc: Color := red
var k, l: -5 .. 5 := iC {both variables initially have the value of iC}
var sensitivity: array Device of Classification
bind var arrayEntry to a0(1) {a0(1) must be a valid reference. arrayEntry is simply
another name for a0(1) over the scope of this declaration}
bind input to UserInput {input is UserInput for the scope of this declaration, but
cannot be changed within the scope}
var a, b: signedInt := iC {a and b initially have the value -1}
var cv: Color
const tenN := 10*n
const hue1 := Hue(red, blue)
const diskIdle: InterruptWord := (0, 1, finishedOk, nullCommand)
var diskControl (at 104#8): InterruptWord := diskIdle
var dateTable: array 1 .. 10-iC of Date
const index: array -1 .. 9 of unsignedInt := (3,1,4,1,5,9,2,6,5,3,6)
var str: string(10)
var shades: array Color of Hue
var jimH, butler, ralph, jimM, gerald: FamilyMember (male)
var Smiths, Joneses: Family
var i, j, x, y, z, max: signedInt
var p, q: Boolean := False
var strP1, strP2: StringRef(100)
var real1, real2: Real.Value
var p1, p2: ↑members
var country: (NotKnown, UnitedStates, Canada, GreatBritain, Other)
var operator: (plus, minus, times)
var col: Color
var anArray: array OneToOneHundred of signedInt

```

Denotations of variables designate an entire variable, or a component of a variable, or a variable referenced by a pointer (see 6.2.6). Variables or constants occurring in examples below are assumed to be declared as indicated above.

Associated with every variable is a *main* variable which is entire; the variable is said to be *part* of its main variable. One variable is *part* of another if, roughly, an assignment to either can change the value of the other, and the space of possible values of the first variable is a (not necessarily proper) subset of the space of possible values of the second variable. The following sections define main variables and part precisely. "Part of" is a transitive relation: if  $x$  is part of  $y$  and  $y$  is part of  $z$  then  $x$  is part of  $z$ . It is also reflexive:  $x$  is part of  $x$ . Two variables are the *same* if and only if each is part of the other. Two variables *overlap* if and only if one is part of the other.

variable ::= entireVariable | componentVariable

### 7.1. Entire variables

An entire variable is denoted by its identifier, and is its own main variable. An entire variable is never part of another entire variable (see 7.4). Hence, two entire variables never overlap.

entireVariable ::= variableIdentifier  
variableIdentifier ::= identifier

### 7.2. Component variables

A component of a variable is denoted by the variable followed by a selector specifying the component. The form of the selector depends on the structuring type of the variable.

componentVariable ::= indexedVariable | fieldDesignator | referencedVariable  
baseVariable ::= variable

Corresponding to each kind of component variable described below, there is a corresponding constant expression which differs from the component variable in only one way: a constant array, record, or module appears in place of the base variable.

#### 7.2.1. *Indexed variables*

A component of an array variable is denoted by the variable followed by an index expression. The main variable of an indexed variable is the main variable of the array variable. The indexed variable is part of the array variable. An indexed variable  $i1$  is part of another indexed variable  $i2$  if and only if either they have the same array variable and the two indexes are equal, or the array variable of  $i1$  is part of  $i2$ .

indexedVariable ::= arrayVariable "(" expression ")"  
arrayVariable ::= baseVariable

The index expression and the index type declared in the definition of the array type must be subranges of the same type. The value of the index expression must be a value of the index type for the program to be legal.

Examples:

```
index(-1)
dateTable((i mod 10-iC) + 1)
shades(green)
```

### 7.2.2. Field designators

A component of a record or module variable, or a formal parameter of the type of any variable, is denoted by the variable followed by the field identifier of the component or parameter. The field identifier of a module component must be exported in the type definition. A field designator is a variable only if the field identifier was declared as a variable; otherwise it is a constant. A variable field designator is readonly if the field identifier was exported as readonly. If a field designator is a variable, its main variable is the main variable of the containing variable, and the field designator is part of the containing variable. A field designator  $f_1$  is part of another field designator  $f_2$  if and only if either their containing variables are the same and their field identifiers are identical, or  $f_1$ 's containing variable is part of  $f_2$ .

```
fieldDesignator ::= containingVariable "." fieldIdentifier
containingVariable ::= baseVariable
fieldIdentifier ::= identifier
```

Examples:

```
str.length
jimM.sex
diskIdle.command {a manifest constant}
realI.mantissa
```

### 7.2.3. Referenced variables

If  $p$  is a pointer variable whose collection  $C$  is of type  $T$ ,  $p$  denotes that variable and its pointer value, whereas  $p\uparrow$  is short for  $C(p)$ , which denotes the variable of type  $T$  referenced by  $p$ . The main variable of a referenced variable is the main variable of the collection to which the variable belongs. The referenced variable is part of the collection variable. A referenced variable  $r_1$  is part of another referenced variable  $r_2$  if and only if either they have the same collection and the two pointers are equal, or the collection of  $r_1$  is part of  $r_2$ .

```
referencedVariable ::= collectionVariable "(" pointer ")" | pointer "\uparrow"
collectionVariable ::= baseVariable
pointer ::= factor
```

Examples:

```
Smithst
Smithst\uparrow.mother
strPI\uparrow.text(1)
```

### 7.3 Scope rules and importing

A scope is a region of text in which an identifier (other than a field identifier) is known with a single meaning. A scope is either

- a type or routine declaration, beginning with the **type**, **procedure**, or **function** and ending at the end of the declaration, or
- a region of the program between the end of a declaration and the next unmatched **end**, or
- a record or module definition, bracketed by **record** or **module** and the matching **end**, or
- a routine definition (see 10.)

A module or routine definition is called a *closed* scope; other scopes are *open*. Note that these closed scopes are nested within the open scopes of the surrounding declarations.

An identifier is *accessible* in a scope S if it is

- declared in that scope, or
- accessible in the enclosing scope if S is open, or
- pervasive in some enclosing scope, or imported into S, or a formal parameter of the type or routine declaration in which S appears, if S is closed.

An identifier must be accessible in S to be used in S in any context except as a field identifier.

New identifiers are declared

- as record or module components,
- as enumerated value identifiers,
- in a declaration at the head of an executable scope,
- as parameters of a for or discriminating case, or
- as formal parameters of a routine or type declaration.

These new identifiers are accessible within the newly established scope. They are not accessible outside of this scope, except that:

Field identifiers of records, or of modules if exported, are accessible outside the scope in a suitable field designator, which is considered to be a continuation of that scope.

If an enumerated type is the definition in a declaration of type T, its value identifiers are declared in the same scope as T, rather than in the inner scope of the type declaration.

Note that the name declared by a module type or routine declaration is *not* declared in the closed scope which is the definition, but in the enclosing scope; it must be imported explicitly into that scope if the definition is recursive. The formal parameters of the declaration, if any, are accessible in the closed scope. Note also that in the case of a module, the type may only be used within the module definition as the object type of a collection (see 6.)

A new identifier may not be introduced which is the same as any other identifier accessible in the scope. Of course, an identifier accessible in the enclosing scope of a closed scope, but not imported or pervasive, is not accessible, and hence may be reused. This is the *only* way in which an identifier can become inaccessible in an inner scope.

An identifier used in a scope and not declared in that scope is said to be *free* in that scope. Any identifier which is free in a closed scope must be accessible in the immediately enclosing scope, and either explicitly *imported* into the closed scope, or declared **pervasive** in some enclosing scope; see 6.2.3 for syntax. An identifier declared **pervasive** is imported, as a constant, into all scopes nested within the one in which it is declared; hence it may not be redeclared in any of these scopes. Only constant identifiers may be declared **pervasive**, since variables cannot be imported as constants.

If a routine is imported into a scope *S*, every identifier which it imports must also be imported into *S*. If a module type is imported into *S*, every identifier imported by the type which is in turn imported by any component of the type which is exported, must also be imported into *S*. Furthermore, in both cases a variable imported **var** into such a module type or routine must be imported **var** into *S*, rather than **readonly**. Thus, it is not possible for a scope to cause any variable to be referenced or modified which the scope could not itself have referenced or modified (except that a called routine may be able to access components of a module, when the caller could only access the module as a whole).

An explicitly imported identifier has the same status as a newly declared one. The imports clause can specify (in the binding condition) for each variable identifier whether it is imported as an ordinary variable, or **readonly** (the default). A **readonly** variable may not be changed explicitly; i.e., it may not be assigned to, or passed as a variable parameter. A **readonly** variable is not a constant, however, since its value may change as a result of statements executed in an enclosing scope where it is not **readonly**. A variable identifier may not be imported as a constant. A constant identifier is always imported as a constant; its binding condition may be **const** or may be omitted.

Any identifier used in a formal parameter list is automatically imported into the closed routine or module body which follows. If an enumerated type is imported, all its enumerated value identifiers are automatically imported. If a record or module type is imported, any of its field names (if it is opaque, any exported field names) can be used as field identifiers in a field designator whose containing variable is of that type.

A closed scope has the property that all its possible interactions with the rest of the world can be determined by examining its imports list, identifiers declared **pervasive** in some enclosing scope, its parameters, and, in the case of a module, its exports list. In the case of a routine no exports list is needed, since nothing is left after the routine returns.

The defining expressions for constants and the index expressions for variable bindings are evaluated when a scope is entered, or when a record or module variable or constant is declared, or when a dynamic record or module variable is created.

Note that a pointer cannot be dereferenced within a given scope unless its collection is accessible in that scope, and cannot be dereferenced to a variable unless the collection is accessible as a variable in that scope; these rules are identical to the rules for indexed variables.

A declaration in Euclid cannot have any side effects, with one exception: a declaration of a module *variable* may have side effects from the execution of the module's initial action, if the module imports any variables.

#### 7.4 Binding

An identifier may be *bound* to a variable when it appears

as a var formal parameter in a procedure declaration (functions cannot have var parameters);  
in a variable binding in a variable declaration.

A variable to which an identifier is bound is said to be *renamed*.

The scope of a binding is the scope of the declaration, and within this scope the identifier represents the variable. That is, the initial value of the identifier is the value of the renamed variable at the time of binding, and the last value assigned to the identifier will be the value of the renamed variable after control finally leaves the scope. If this variable is part of an array, its index is evaluated when the scope is entered; if it is part of a referenced variable, the pointer is evaluated when the scope is entered.

The type and range of the identifier being bound must be the same as the type and range of the renamed variable to which it is bound (but see 10 for the use of parameter). A component of a packed structure or a machine-dependent record must not appear as a renamed variable. Note that this does not prevent discrimination of a packed variant record (see 9.2.2.2), since in that case it is the entire record which is renamed, not a component.

Any variable imported by a scope is considered to be renamed. For open scopes, any variable free in the scope is considered to be imported by the scope, and hence to be renamed. A variable is renamed even if it is bound or imported readonly (but not if it is passed as a constant parameter), and even if it is readonly in the outer scope.

In order to allow a simple description of the rules for renaming variables, we will assume for the rest of this section that a procedure does not import any variables; the initial and final actions of a module are considered to be parameterless procedures for this purpose. Any procedure which does import variables is to be rewritten as a procedure which accepts the imported variables as additional variable formal parameters, and every call is rewritten to supply the same variables as additional actual parameters. This also applies to procedures in modules: if a component of the module is imported as a variable by the procedure, that component is supplied as an additional actual parameter (in spite of the fact that it might not be exported). The rewritten program will behave exactly like the original one.

In order to ensure that the rewritten program is a legal one, however, we must (and do) impose the following requirement on the original program: any free variable in a procedure must have the property that it would be accessible as a variable in every scope which contains a call of the procedure, if the field identifiers required to reach it were exported as variables.

The language ensures that an entire variable can never overlap (see 7.1) any other variable accessible in the same scope which has a different main variable, or in other words that

the value of an entire variable can change only  
as the result of assignment to that variable or one of its parts, or  
as a result of a procedure call in which that variable was the main variable  
of an actual parameter corresponding to a variable formal parameter;  
an assignment to an entire variable can never change the value of any other variable  
which is accessible in the scope containing the assignment, except one of its own  
parts.

To prevent binding from destroying this non-overlap property, the following restriction is imposed: no two variables which are renamed on entry to a scope can overlap. If the compiler cannot determine whether or not two variables overlap (e.g.,  $a(i)$  and  $a(j)$  overlap iff  $i=j$ ), it will assume that they don't, and generate a legality assertion to that effect for the verifier to deal with. Note that variable identifiers which it is illegal to access in a scope because of this rule are *not* therefore inaccessible and hence are not eligible for redeclaration. An identifier is accessible everywhere in its scope, except inside nested closed scopes which do not import it.

In general, identifiers that are declared as constants cannot cause any aliasing problems, since their values can always be copied. Of course the compiler is free to use a pointer rather than copy the value if it can determine that the meaning of the program is the same; this will certainly be true if the variable involved does not overlap any variable accessible in the same scope. In other cases the value must be copied.

Copying may be very inefficient for large arrays or records. Hence we impose a stronger rule in this case: if a large variable  $v$  is accessible in a scope as a constant, no variable which overlaps  $v$  can be renamed on entry to the scope. The definition of "large" is implementation-dependent. If the programmer really wants a large array or record to be copied, he can declare a constant for that purpose; unlike passing a constant parameter, a constant declaration looks like an operation which makes a copy, and indeed it generally does, unless the constant is manifest.

A parameterized type with a large actual parameter which is a variable poses a similar problem, since in general the value will have to be copied when such a type is used to declare an identifier, unless the variable is not modified in the scope of the declaration. Hence the same restriction is imposed in this situation: the compiler will reject a program which requires copying a large value in this way.

## 8. Expressions

*"Grant me some wild expressions, Heavens, or I shall burst."*  
 Farquhar, *The Constant Couple*, V, iii

Expressions are constructs denoting rules of computation for obtaining values of variables and generating new values by the application of operators. Expressions consist of operands (i.e., variables and constants), operators, and functions.

The rules of composition specify operator *precedences* according to seven classes of operators. The multiplying operators have the highest precedence, then the adding operators, then the relational operators, then **not**, then **and**, then **or** and finally, with the lowest precedence,  $\rightarrow$ . Sequences of operators of the same precedence are executed from left to right.

Since functions cannot have side effects, the order of evaluation of operands in an expression need not be defined.

The rules of precedence are reflected by the following syntax:

```

factor ::= variable | literalConstant | constantIdentifier | functionDesignator | set |
          "(" expression ")" | "-" factor
set ::= setTypeIdentifier "(" elementList ")"
elementList ::= element { "," element } | all | empty
element ::= expression | simpleType
term ::= factor | term multiplyingOperator factor
sum ::= term | sum addingOperator term
relation ::= sum | sum relationalOperator sum | sum [ not ] in simpleType
negation ::= relation | not relation
conjunction ::= negation | conjunction and negation
disjunction ::= conjunction | disjunction or conjunction
expression ::= disjunction | disjunction "->" disjunction
  
```

Expressions in an element list for a set of type  $T = \text{set of } U$  must all be of type  $U$ .  $T()$  denotes the empty set of type  $T$ ,  $T(\text{all})$  denotes the set containing all the elements of  $U$ , and  $T(x..y)$  denotes the set of all values in the interval  $x..y$ . If  $V$  is a subrange of  $U$ ,  $T(V)$  is an abbreviation for  $T(V.\text{first}..V.\text{last})$ .

Note that the operators on sets, summarized in 6.2.5, can be used to perform bitwise logical operations, and in fact these operators are intended to be implemented with the machine's logical operations on words.

Examples:

Factors:

$$\begin{array}{l} x \\ 15 \\ (x+y+z) \\ \text{Abs}(x+y) \\ \text{Hue(blue, col, green)} \\ \text{Hue(all)} \\ \text{SymSet}(1, 5, -4 .. -1, 2) \\ -x \end{array}$$

Terms:

$$\begin{array}{l} x^*y \\ i \text{ div } (1-i) \\ x \text{ mod } (5^*y) \end{array}$$

Sums:

$$\begin{array}{l} x+y \\ \text{hue1 xor shades(red)} \\ i^*j+1 \\ \text{hue1} - \text{Hue(blue)} \end{array}$$

Relations:

$$\begin{array}{l} x = 15 \\ x \text{ not}= 15 \\ p <= q \\ (i < j) = (j < k) \\ cv \text{ in } \text{hue1} \\ cv \text{ not in } \text{shades(orange)} \\ i \text{ in } \text{oneToOneHundred} \\ i \text{ not in } 25 .. (x^*5) \end{array}$$

Negations:

$$\begin{array}{l} \text{not } (p \text{ not}= q) \\ \text{not } q \end{array}$$

Conjunctions:

$$\begin{array}{l} x \leq y \text{ and } y \leq z \\ p \text{ and not } q \end{array}$$

Disjunctions:

$$p \text{ or } (x > y)$$

Expressions:

$$\begin{array}{l} \text{False} \rightarrow p \text{ or } (x > y) \\ a^*a > b^*b \rightarrow (\text{Abs}(a) > \text{Abs}(b)) \end{array}$$

## 8.1. Operators

The compiler is expected to check that no overflow will occur during the evaluation of an expression; if it is unable to verify this, it must put out a legality assertion for the verifier to check (see 6.1.2).

The types of the operands must be the same as the types specified below, or subranges of those types. A consequence is that a value whose type is exported from a module cannot be an operand in an expression outside the module, except perhaps of the "=" operator.

### 8.1.1. Multiplying operators

`multiplyingOperator ::= "*" | div | mod`

<u>operator</u>	<u>operation</u>	<u>type of operands</u>	<u>type of result</u>
*	multiplication set intersection	integer any set type T	integer T
div	division with truncation	integer	integer
mod	modulus	integer	integer

The `div` operator truncates toward zero, so that  $-(a \text{ div } b) = -a \text{ div } b$ . Also,  $a \text{ div } -b = -a \text{ div } b$ . The `mod` operator is defined by  $a \text{ mod } b = a - ((a \text{ div } b) * b)$ . The right operand of `div` or `mod` must be non-zero.

### 8.1.2. Adding operators

`addingOperator ::= "+" | "-" | xor`

<u>operator</u>	<u>operation</u>	<u>type of operands</u>	<u>type of result</u>
+	addition set union	integer any set type T	integer T
-	subtraction set difference	integer any set type T	integer T
xor	symmetric difference	any set type T	T

When used as an operator with one integer operand only, `-` denotes sign inversion.

### 8.1.3. Relational operators

`relationalOperator ::= "=" | not "=" | "<" | "<=" | ">" | ">=" | in | not in`

<u>operator</u>	<u>type of operands</u>	<u>result</u>
= not =	most types	Boolean
< >	any enumerated or subrange type	Boolean
<= >=	any enumerated, subrange or set type	Boolean
in	any enumerated or subrange type	Boolean
not in	any enumerated or subrange type and its set type, respectively	Boolean
	any enumerated or subrange type and an index type (not value), respectively.	

Notice that all enumerated types define *ordered* sets of values.

The operators <=and >= stand for less than or equal, and greater than or equal respectively. They may also be used for comparing values of set type, and then denote set inclusion. If  $p$  and  $q$  are Boolean expressions,  $p=q$  denotes their equivalence.

#### *8.1.4 Other operators*

<u>operator</u>	<u>operation</u>	<u>type of operands</u>	<u>type of result</u>
<b>not</b>	logical negation	Boolean	Boolean
<b>and</b>	logical "and"	Boolean	Boolean
<b>or</b>	logical "or"	Boolean	Boolean
<b>-&gt;</b>	logical implication	Boolean	Boolean

The right operand of **and** need not be legal if the left operand is False; the right operand of **or** need not be legal if the left operand is True; the right operand of **->** need not be legal if the left operand is False.

## 8.2. Function designators

A function designator specifies the evaluation of a function. It consists of the identifier or field designator designating the function, and a list of actual parameters. The parameters are expressions, and their values are substituted for the corresponding formal parameters (see 9.1.2, 10, and 11).

```
functionDesignator ::= function [ "(" expression { "," expression } ")" ] |
                     typeConverter "(" expression ")"
function ::= [ containingVariable ":" ] functionIdentifier
functionIdentifier ::= identifier
```

Examples:

```
FindMax(Index)
Gcd(147, k)
Power(Index(i), str.length)
Real.Add(real1, Real.number(314159,1))
```

## 9. Statements

*"The statements was interesting, but tough."*  
*Huckleberry Finn, Ch. 17*

Statements denote algorithmic actions, and are said to be *executable*.

statement ::= simpleStatement | structuredStatement

### 9.1. Simple statements

A simple statement is a statement of which no part constitutes another statement. The empty statement consists of no symbols and denotes no action.

simpleStatement ::= assignmentStatement | procedureStatement | escapeStatement | assertStatement | emptyStatement

emptyStatement ::= empty

#### 9.1.1. Assignment statements

The assignment statement serves to replace the current value of a variable by a new value specified as an expression.

assignmentStatement ::= variable ":"= expression

The variable and the expression must be of the same type, with the following exceptions being permitted:

1. The types of the expression and the variable are both subranges of the same type. If the value of the expression is not within the subrange of the variable's type, the program is illegal.
2. The type of the variable may have any as an actual parameter of a type where the type of the expression has some specific value (see 6.4).

Note that assignment is not allowed if the type  $T$  of the variable is not *assignable*, or if the variable is readonly. A type is not assignable if it is a collection type, or if it is an exported type for which assignment was not exported, or if it is a structured type which has a variable component whose type is not assignable.

Examples:

```
x := y+z
p := i in 1..99
p := (1<=i) and (i<100)
shades(blue) := Hue(blue, Color.Succ(c))
real1 := real2
```

#### 9.1.2. Procedure statements

A procedure statement serves to execute the procedure denoted by the procedure identifier. The procedure statement may contain a list of *actual parameters* which are assigned or bound to the corresponding *formal parameters* declared in the procedure declaration (cf.

10). The correspondence is established by the positions of the parameters in the lists of actual and formal parameters, respectively. There are two kinds of parameters: *constant* parameters and *variable* parameters; routine and type parameters are not permitted.

In the case of a *constant parameter*, the actual parameter must be an expression (of which a variable is a simple case). The corresponding formal parameter represents a local constant of the called procedure, and the current value of the expression is the value of this constant. As in the case of a constant declaration, the type of the actual parameter must be assignable, and assignment-compatible with the type of the formal (see 6.4). Note that a constant formal parameter is not a manifest constant, since its value is not known at compile-time.

In the case of a *variable parameter*, the actual parameter must be a variable, and the corresponding formal parameter is bound to this actual variable (see 7.4) during the entire execution of the procedure. The types must be the same. A variable parameter must be used whenever the parameter represents a result of the procedure.

```
procedureStatement ::= procedure [ "(" expression { "," expression } ")" ]
procedure ::= [containingVariable "."] procedureIdentifier
procedureIdentifier ::= identifier
```

Examples:

```
TreeSort(DA)
ZeroArray(DA)
Replace(str, i, 3, "***")
```

### 9.1.3 Escape statements

An escape statement serves to indicate that further processing should continue at the statement following the smallest enclosing repetitive statement (*exit*), or that control should return immediately from the routine currently being executed (*return*). Note that any module variables which are destroyed as a result of the escape will have their final actions executed first. The *when* clause, if present, makes execution of the escape conditional. Thus, the statement

S when B  
is equivalent to  
    if B then S end if.

An expression must not appear in a *return* statement unless the statement is in a function body, and in that case the type of the expression must be assignment-compatible with the type of the function's result value.

```
escapeStatement ::= escapeBody [ when expression ]
escapeBody ::= exit | return | return expression
```

Example:

```

begin
var flag : (a, b, finished) := finished
for ... loop
...
flag := a; exit
...
flag := b; exit
...
end loop
case flag of
  a => ... end a
  b => ... end b
  finished => ... end finished
end case
end

```

#### 9.1.4 Assert statements

An assert statement introduces an assertion (see 6.2.3) which is supposed to hold whenever control reaches that point in the program. The compiler treats it as a comment, as it does with the assertions supplied by invariant, pre and post clauses, unless the assertion is a Boolean expression, and the checked option is specified for an enclosing block, in which case the Boolean expression is evaluated, and execution of the program is terminated if it is False.

assertStatement ::= assert assertion

Examples:

```

assert x < y and y < z
assert {z*(w**i) = x**y}

```

## 9.2. Structured statements

Structured statements are constructs composed of other statements which have to be executed either in sequence (compound statement and block), conditionally (conditional statements), or repeatedly (repetitive statements).

structuredStatement ::= compoundStatement | block |
conditionalStatement | repetitiveStatement

#### 9.2.1. Compound statements and blocks

The compound statement specifies that its component statements are to be executed in the same sequence as they are written. Note that a compound statement is a statement, and has no brackets; hence a sequence of statements can be written wherever a single statement can be written.

compoundStatement ::= statement { ";" statement }

Example:  $z := x; x := y; y := z$

A block is a compound statement within which new identifiers can be introduced. The symbols **begin** and **end** act as brackets to delimit the scope of the new identifiers. If a scope *S* starts with **checked**, each legality assertion in *S*, and each assertion in the source text of *S* which is a Boolean expression, is compiled into a runtime check, which aborts execution of the program if the assertion is False. If *S* starts with **not checked**, any occurrence of **checked** in an enclosing scope is ineffective in *S*.

```
block ::= begin executableScope end
executableScope ::= checkedClause [ declaration ";" ] statement
```

**Example:**

```
begin
const twoX := 2*x
var w: signedInt
w := twoX*twoX-x
begin
bind y to w;
y := twoX*twoX*twoX+y      { really means w := twoX*twoX*twoX+w}
end
end
```

#### 9.2.2. Conditional statements

A conditional statement selects for execution a single one of its component statements.

```
conditionalStatement ::= ifStatement | caseStatement
```

##### 9.2.2.1. If statements

The if statement specifies that a statement is to be executed only if a certain condition (Boolean expression) is True. If it is False, then either no statement is to be executed, or the statement following the symbol **else** is to be executed.

**The statement**

**if a then b elseif ... end if**  
is an abbreviation for  
**if a then b else if ... end if end if.**

```
ifStatement ::= if expression then executableScope elseifClause
[ else executableScope ] end if
```

```
elseifClause ::= { elseif expression then executableScope }
```

The expression between the symbols **if** or **elseif** and **then** must be of type Boolean.

**Examples:**

```
if x<15 then z := x+y; cv := blue else cv := red; z := 0 end if
if p1 not= members.nil then p1 := p1↑.relations; p2 := members.nil end if
if str.text(1) = $$$ then country := UnitedStates
elseif str.text(1) = $# then country := GreatBritain
else country := NotKnown
end if
```

### 9.2.2.2. Case statements

The case statement consists of an expression (the selector) and a list of elements, each labelled by a set of manifest constants of the type of the selector. It specifies that the one element is to be executed whose label contains the current value of the selector. A special label *otherwise* can be used to label a statement which should be executed if none of the other labels contains the current value of the selector. If none of the labels contains the selector, and there is no *otherwise*, the program is illegal. Each element, except the *otherwise* element, must be terminated with *end* followed by one of the constants in its label.

If the selector is discriminating an object, the parameter bound to the object is automatically declared in each case list element, either as a constant whose value is the expression in the object, or as a variable bound to the variable in the object. The expression or variable in the object must be a variant record, say of type *T(any)* or *T(unknown)*, and the tag of this record, specified by the *on* clause, is used to select one of the case list elements; in this situation, each case label list of the discriminating case statement must correspond to exactly one variant of the record. Within the element selected by a particular value of the tag, say *red*, the parameter has the type *T(red)*. Thus with the type declaration

```
type T(tag: (red, green, ...)) = record
  ...
  case tag of
    red => ...
    green => ...
  ...
end case
end T
```

the program

```
var anyx: T(any); ...;
with x := anyx case tag of
  red => ...
  green => ...
end case
```

is equivalent to

```
var anyx: T(any); ...;
case anyx.tag of
  red => const x: T(red) := anyx; ...
  green => const x: T(green) := anyx; ...
...
end case
```

except that the constant declarations in the latter would not be legal, because it is illegal to assign a *T(any)* to a *T(red)*.

```

caseStatement ::= simpleCase | discriminatingCase
simpleCase ::= case expression of caseBody end case
discriminatingCase ::= with object case identifier of caseBody end case
caseBody ::= caseListElement { ";" caseListElement } otherwiseElement [ ";" ]
caseListElement ::= caseLabelList ">" executableScope end caseLabel | empty
otherwiseElement ::= ";" otherwise ">" executableScope | empty
object ::= [ const ] parameter ":" expression |
varBindingCondition parameter bound to variable
parameter ::= identifier

```

Examples:

```

case operator of
  plus => x := x+y end plus
  minus => x := x-y end minus
  times => x := x*y end times
end case

case i of
  1 => cv := red end 1
  2 => cv := blue end 2
  3,8 => cv := green end 3
  4..6,9,10 => cv := yellow end 4
  otherwise => cv := purple
end case

with s bound to anyStream case dev of {begin new line}
  display => s.height := s.height +1 end display
  tape, disk =>
    s.position := s.position +1
    s.buffer(s.position) := $N
  end tape
  keyboard => end keyboard {don't send characters to input device}
  otherwise => {also null}
end case

```

### 9.2.3. Repetitive statements

Repetitive statements specify that certain statements are to be executed repeatedly. If a bound on the number of repetitions is known before the repetitions are started, or if the repetition is controlled by a generator, the for statement is the appropriate construct; otherwise the loop statement should be used.

A repetitive statement introduces a new scope. The declarations of this scope take effect before the repetition starts, and remain in effect until the end of the repetition. The statements of the scope are executed repeatedly.

```
repetitiveStatement ::= loopStatement | forStatement
```

### 9.2.3.1. Loop statements

The statements in the scope are executed repeatedly until control leaves the scope through an escape statement.

```
loopStatement ::= loop executableScope end loop
```

Examples:

```
loop; exit when Color.Ord(tc) = x; tc := Color.Succ(tc) end loop
loop
  if Odd(i) then z := z*x end if
  i := i div 2
  exit when i=0
  x := x*x
end loop
loop k := i mod j; i := j; j := k; exit when j = 0; end loop
```

### 9.2.3.2. For statements

The for statement indicates that a statement is to be repeatedly executed while a progression of values is assigned to a new constant identifier called the *parameter* or *controlled constant* of the for statement.

```
forStatement ::= for parameter generator [ ";" ] loop executableScope end loop
generator ::= in moduleType | [ decreasing ] in indexType | in setExpression
setExpression ::= expression
```

The parameter is declared as a constant in the scope. The type of the parameter is the type of the value component of the module type, the type of the elements of the index type, or the base type of the set.

A module type generator is a module type which has three components with special names: variables called *value* and *stop*, and a procedure called *Next*. These names must be exported. A for statement of the form

```
for v in moduleTypeGenerator loop LoopBody end loop
is equivalent to the block
```

```
begin var crec: moduleTypeGenerator;
  loop exit when crec.stop
    begin const v:=crec.value; LoopBody end
    crec.Next
  end loop
end
```

The initial and final actions in the declaration of the generator module type can perform any initialization or cleanup which may be appropriate; note that the final action is executed whenever control finally leaves the for statement, whether normally or via an escape statement.

A for statement with an index type generator, of the form

```
for v in AnIndexType loop LoopBody end loop
```

is equivalent to the block

```
begin var vv:AnIndexType := AnIndexType.first
  if vv <= AnIndexType.last then
    loop
      const v:=vv
      LoopBody
      exit when vv=AnIndexType.last
      vv:=AnIndexType.Succ(vv)
    end loop
  end if
end
```

If decreasing is present, interchange first and last, and replace Succ by Pred and <= by >=.

A for statement with a set expression generator, of the form

```
for v in SetExp loop LoopBody end loop
```

is equivalent to the statement

```
begin const se:=SetExp
  for v in SetExp.BaseType
    loop
      if v in se then LoopBody end if
    end loop
  end
```

Note that if the generator imports no variables, the loop body and the generator are independent, and interact only through the parameter values which are passed from the generator to the body. Thus termination can be proved solely as a property of the generator.

Examples:

```
for lm in OneToOneHundred
  loop if anArray(lm)>max then max := anArray(lm) end if end loop
  for ci decreasing in Color loop Q(ci) end loop
```

#### 9.2.4 Other uses of binding

If a record variable is to be used a number of times in field designators, it is often convenient to bind a short identifier to it (see 7.4). Note that the binding is fixed on entry to the scope.

Example:

```
begin bind d to dateTable(i+5);
  if d.month = 12 then d.month := 1; d.year := d.year+1
  else d.month := d.month+1
  end if
```

end

is equivalent to

```
if dateTable(i+5).month = 12 then
    dateTable(i+5).month := 1
    dateTable(i+5).year := dateTable(i+5).year+1
else dateTable(i+5).month := dateTable(i+5).month+1
end if
```

and, also equivalent to

```
begin
bind d to dateTable (i+5)
bind (m to d.month, y to d.year)
if m = 12 then m := 1; y := y+1 else m := m+1 end if
end
```

## 10. Procedure declarations

*"But a name for an effect."*  
Cowper

A procedure declaration serves to define a part of a program, and to associate an identifier with it so that it can be activated by procedure statements; a function declaration (see 11.) plays a similar role. Collectively, procedures and functions are called *routines*.

A machine-code routine is exactly like an ordinary routine, except that its body is a sequence of machine instructions, represented as manifest integer constants according to an implementation-dependent convention. An implementation may define a more elaborate syntax for code bodies. Machine code routines may only appear in machine-dependent modules.

```

procedureDeclaration ::= procedureHeading "=" routineDefinition
routineDefinition ::= importsClause preAssertion postAssertion routineBody
routineBody ::= begin executableScope end identifier | forward | codeBlock
codeBlock ::= code manifestConstant { ";" manifestConstant } end identifier

```

The *procedure heading* specifies the identifier naming the procedure, and the formal parameter identifiers (if any). The parameters are either constant or variable parameters (see also 9.1.2).

The standard representation of a routine identifier must be defined by the implementation, so that a routine can be the argument of an explicit type conversion. A linkage between a machine code routine and a Euclid routine *R* can then be done by making a declaration of the form

```
var Rlink : routineLink (at 100) := routineLink<<=procedure(R)
```

and writing in the machine code body an appropriate jump to the routine address stored at 100. The type *routineLink* would of course have to be properly declared in the program.

If the heading is prefixed by **inline**, this is a hint to the compiler that the procedure body should be copied at each call. Such copying tends to result in faster execution, at the expense of a larger object program. The meaning of the program is not changed by the **inline** prefix. However, an **inline** routine may not have a **forward** body or import its own name (i.e., may not be recursive).

```

procedureHeading ::= [ inline ] procedure identifier formalParameterList
formalParameterList ::= "(" formalSection { "," formalSection } ")" | empty
formalSection ::= pervasive bindingCondition identifier { "," identifier }
               ":" typeDefinition
preAssertion ::= pre assertion ";" | empty
postAssertion ::= post assertion ";" | empty

```

A formal section without **const**, **var**, or **readonly** implies that its constituents are constants.

A type specification for a formal parameter may have actual parameters which are other formal parameters; thus

```

procedure f( $n$ : 0..1000,  $a$ : array 1.. $n$  of signedInt) ...
is a legal declaration. This procedure might be called as follows:
begin var aa: array 1..200 of signedInt; ... f(200, aa); ... end

```

Furthermore, in order to reduce the proliferation of parameters which would otherwise be required, we make the following rule: the type of a formal parameter may be a parameterized type with some or all of the actual parameters of the type replaced by the symbol parameter. Each actual parameter of the type for which parameter appears is treated as though it appeared as an additional formal parameter of the procedure, and the appropriate actual parameter of the procedure is supplied in every call. Thus

```

type Ta( $n$  unsignedInt)=array 1.. $n$  of signedInt; procedure f( $a$ : Ta(parameter)) ...
is also legal and is equivalent to the previous declaration of  $f$ , except that all the calls on  $f$  will be modified appropriately. The previous call would be written

```

```

... f(aa) ...
and would be modified to become
... f(200, aa) ...

```

The use of the procedure identifier in a procedure statement within its declaration implies recursive execution of the procedure.

Examples of procedure declarations:

```

type DataArray( $n$ : 1..256) = array 1.. $n$  of signedInt;
procedure TreeSort(var  $a$ : DataArray(parameter)) =
{This procedure is a version of Floyd's TreeSort algorithm in CACM, 7 (1964), p.
701. TreeSort sorts the array  $a$  in ascending order}
post { $\{(a \text{ in } \text{Perm}(a')) \text{ and } j \text{ in } 1 .. a.n-1) \rightarrow a(j) \leq a(j+1)\}$ 
begin type Index =  $a.\text{IndexType}$ 
  inline procedure Swap( $i1, i2$ : Index) =
    imports (var  $a$ )
    post { $\{a \text{ in } \text{Perm}(a') \text{ and } a(i1)=a'(i2) \text{ and } a(i2)=a'(i1)\}$ 
      begin
        const  $t := a(i1)$ 
         $a(i1) := a(i2); a(i2) := t$ 
      end Swap;

    procedure SiftUp( $low, high$ : Index) =
      imports(var  $a$ )
      pre { $\{j \text{ in } 2*(low+1) .. high \rightarrow a(j) \leq a(j \text{ div } 2)\}$ }
      post { $\{j \text{ in } 2*low .. high \rightarrow (a(j) \leq a(j \text{ div } 2) \text{ and } a \text{ in } \text{Perm}(a'))\}$ 
        begin var son: Index :=  $low$ 
          loop const father := son
            son :=  $2*father$ 
            return when son > high
            if son < high and  $a(\text{son}) < a(\text{son}+1)$  then son := son+1 end if
            return when  $a(\text{son}) \leq a(\text{father})$ 
            Swap(son, father)
            assert { $\{j \text{ in } 2*low .. son \rightarrow a(j) \leq a(j \text{ div } 2)\}$ }
          end loop
        end SiftUp
      
```

```

for i decreasing in 1 .. (Index.last div 2)
  loop
    SiftUp(i, Index.last)
    assert {Sifted(2*i, Index.last)}
  end loop
for i decreasing in 1 .. Index.last-1
  loop
    Swap(1, i+1)
    SiftUp(1, i)
  end loop
end TreeSort

type DataArraySegment(m, n: 1..256) = array m..n of signedInt

procedure ZeroArray(var a: DataArraySegment(parameter, parameter)) =
post {i in a.m .. a.n -> a(i)=0}
begin
  for i in a.IndexType loop a(i) := 0 end loop
end ZeroArray

procedure Replace(var target: string(parameter),
                 first, len: StringIndex, source: string(parameter)) =
pre (target.length+source.length-len <= target.maxLength)
post { (i in 1..first-1 -> target.text(i) = target'.text(i)) and
      (i in first .. first+source.length-1 ->
       target.text(i)=source.text(i-first+1)) and
      (i in first+source.length .. target.length+source.length-len ->
       target.text(i) = target'.text(i+len-source.length)) and
      (target.length = target'.length + source.length-len)}
begin
  const offset := source.length-len
  bind (var tgt to target.txt, var tl to target.length)
  if offset > 0 then
    for i decreasing in first+len .. tl loop tgt(i+offset) := tgt(i) end loop
  elseif offset < 0 then
    for i in first+len .. tl loop tgt(i+offset) := tgt(i) end loop
  end if
  tl := tl+offset
  for i in 1 .. source.length loop tgt(first+i-1) := source.text(i) end loop
end Replace

procedure Append(var target: string(parameter), source: string(parameter)) =
pre (target.length+source.length <= target.maxLength)
post {(target.length = target'.length + source.length) and
      (i in 1..target'.length -> target.text(i) = target'.text(i)) and
      (i in 1 .. source.length -> target.text(i+target'.length)) = source.text(i)}
begin
  for i in 1 .. source.length
    loop
      target.text(i+target.length) := source.text(i)
    end loop
  target.length := target.length + source.length
end Append

```

## 11. Function declarations

*"The Form remains, the Function never dies."*

Wordsworth

Function declarations serve to define parts of the program which compute a value. A function is activated by the evaluation of a function designator (cf. 8.2) which is a constituent of an expression.

functionDeclaration ::= functionHeading "=" routineDefinition

The function heading specifies the identifier naming the function, the formal parameters of the function, and the type of the function.

functionHeading ::= [ inline ] function identifier formalParameterList

returns resultName typeDefinition

resultName ::= identifier ":" | empty

Functions may return values of any assignable type (see 9.1.1). If the result name is supplied, then within the function declaration there must be one or more assignment statements assigning a value to the result name, and the value of the result name when the function returns determines the value of the function. If no result name is supplied, the result must be supplied in every return statement. A return statement without any value is supplied automatically just before the end of the body. A machine-code function returns its value by an implementation-defined convention.

Occurrence of the function identifier in a function designator within its declaration implies recursive execution of the function.

A function may not have variable parameters, or import anything var (although importing a variable readonly is legal); hence, a function cannot have side effects, but must return the same value whenever it is called with the same actual parameters.

Examples:

```

function FindMax(a: DataArraySegment(parameter, parameter))
    returns index: signedInt =
    post {k in a.m .. a.n -> a(index) >= a(k)}
        begin
            index := a.m
            for i in a.m+1 .. a.n
                loop
                    assert {k in a.m .. i-1 -> a(index) >= a(k)}
                    if a(i) > a(index) then index := i end if
                end loop
            end FindMax

function Gcd(m, n: signedInt) returns signedInt =
    imports(Gcd)
    begin if n=0 then return m else return Gcd(n, m mod n) end if end Gcd

```

```

function Power(x: signedInt, y: unsignedInt) returns z: signedInt =
begin var w: signedInt; var i: unsignedInt
      w := x; i := y; z := 1
      loop assert {z*(w**i) = x**y}
      exit when i = 0
      if Odd(i) then z := z*w end if
      i := i div 2
      w := w*w
      end loop
      assert {z = x**y}
end Power

function Substr(s: string(parameter), first: StringIndex, len: StringLength)
returns r: string(len) =
pre first+len <= s.length+1
post {(i in 1..len -> r.text(i) = s.text(i+first-1)) and r.length = len}
begin
  r.length := len
  for i in 1..len loop r.text(i) := s.text(i+first-1) end loop
end Substr

function Catenate(s1: string(parameter), s2: string(parameter), size: StringLength)
returns r: string(size) =
pre s1.length + s2.length <= size
post {(r.length = s1.length + s2.length) and
      (i in 1..s1.length -> r.text(i) = s1.text(i)) and
      (i in 1..s2.length -> r.text(i+s1.length) = s2.text(i))}
begin
  r.length := s1.length + s2.length
  for i in 1 .. s1.length loop r.text(i) := s1.text(i) end loop
  for i in 1 .. s2.length loop r.text(i+s1.length) := s2.text(i) end loop
end Catenate

```

## 12. Programs

*"All are but parts of one stupendous whole."*  
Pope, *An Essay on Man*

A Euclid program consists of a sequence of module type declarations, possibly prefixed by an include clause which causes additional text to be inserted into the program. The include clause is a list of items, each of which names a file containing the text of a Euclid program; the file is named by a literal string, according to an implementation-defined convention. If **from** is present, only the named module types are included; otherwise all the declarations in the file are included. If the same type identifier from the same file is included more than once, duplicates are suppressed. If different files contain types with the same name, however, an error results because of the normal Euclid rule which forbids redeclaration of names.

An implementation may use some method other than the textual substitution described above to provide this facility. In particular, it may take advantage of the fact that an included file has already been compiled. Thus the structure of compilation units is intended to facilitate separate compilation (although not to require it).

The report does not specify how the module types declared in programs are instantiated to start a program.

```

program ::= compilationUnit
compilationUnit ::= [ includeClause ";" ] typeDeclaration { ";" typeDeclaration }
includeClause ::= include includelItem { ";" includelItem }
includelItem ::= [ id { "," id } from ] fileName
fileName ::= literalString

```

Example:

```

type NumberTable = module exports(Search, Delete, Insert)
{This module implements a table of numbers, e.g., currently open accounts, as an
associative memory}
pervasive const tableSize := 763
pervasive type TableIndex = 1 .. tableSize
pervasive type CyclicScan(item: signedInt) = {a generator for a for loop}
    module exports (Next, value, stop)
        const start := (item mod tableSize)+1
        var value: TableIndex := start
        var stop: Boolean := False
        procedure Next =
            imports(var value, start, var stop)
            begin
                if value = tableSize then value := 1
                else value := value+1 end if
                stop := (value not= start)
            end Next
    end CyclicScan

```

```

type State = (fresh, full, deleted)
type TableEntry(flag: State) =
    record
        case flag of
            full => var key: signedInt end full
            otherwise =>
        end case
    end TableEntry

var table: array TableIndex of TableEntry(any)

function Search(key: signedInt) returns Boolean =
    imports(table)
    begin
        for i in CyclicScan(key)
            loop
                with entry := table(i) case flag of
                    fresh => return False end fresh
                    full =>
                        return True when entry.key = key;
                        end full;
                    otherwise =>
                end case;
            end loop;
        return False;
    end Search;

procedure Delete(key: signedInt) =
    imports(var table)
    begin
        const deletedEntry: TableEntry(deleted) := ();
        for i in CyclicScan(key)
            loop
                with entry := table(i) case flag of
                    full =>
                        if entry.key = key then
                            table(i) := deletedEntry;
                            return
                        end if
                    end full
                    fresh => return end fresh
                    otherwise =>
                end case;
            end loop;
    end Delete;

procedure Insert(key: signedInt) =
    imports(var table, Search)
    begin
        return when Search(key) {if already there};
        for i in CyclicScan(key)
            loop
                case table(i).flag of

```

```
loop
  case table(i).flag of
    fresh, deleted =>
      var t: TableEntry(full)
      t.key := key
      table(i) := t
      end fresh
    otherwise =>
  end case
end loop
assert False {table will never be full}
end Insert

const freshEntry: TableEntry(fresh) := ()

initially
begin
  for i in table.IndexType loop table(i) := freshEntry end loop
end
end NumberTable
```

### 13. A standard for implementation and program interchange

*"That's not a regular rule: You invented it just now."*

*'It's the oldest rule in the book,' said the King.*

*'Then it ought to be Number One,' said Alice."*

*Alice in Wonderland, Ch. 12*

One motivation for the development of Euclid was the need for a powerful and flexible language that could be reasonably efficiently implemented on most computers. Its features are defined without reference to any particular machine in order to facilitate the interchange of programs. To establish a reasonable minimum standard for Euclid implementations, the following requirements are imposed on every implementation.

1. Word symbols, such as `begin`, `end`, etc., may be written as a sequence of letters (without surrounding escape characters). They may not be used as identifiers. An implementation may also allow such symbols to be written in other ways (e.g. in boldface), provided there is a straightforward transformation into the representation as a sequence of letters.
2. Blanks, ends of lines, and comments are defined as *separators*. An arbitrary number of separators may occur between any two consecutive Euclid symbols, with the following restriction: no separators may occur within identifiers, numbers, and word symbols.
3. At least one separator must occur between any pair of consecutive identifiers, numbers, or word symbols.
4. The implementation may set limits on the size and complexity of the source program. However, these limits must be chosen from the following list, and must not be more restrictive than indicated below. An implementation should not reject a program for exceeding some limit not on this list; it may accept programs which exceed any of these limits.
  - a) The range of `unsignedInt` (must include  $0..2^{16}-1$ ). The range of `signedInt` (must include  $-2^{15}+1..2^{15}-1$ ). It is recommended, but not required, that larger subranges of integer than these be permitted, say up to  $0..2^{32}-1$  and  $-2^{31}+1..2^{31}-1$ .
  - b) The maximum number of elements in the base type of a set (at least 16).
  - c) Depth of nesting of scopes (at least 31).
  - d) Depth of nesting of parentheses in an expression (at least 7). Number of basic symbols in an expression (at least 50).
  - e) The total number of identifiers accessible in a scope (at least 200). The total number of identifiers in the program (at least 1000).
  - f) The number of non-compound statements and declaration parts in the source program (at least 2000).

- g) The maximum number of characters in an identifier (at least 50).
- h) The value of stringMaxLength (at least 255).

### 13.1 Representation of special symbols

The preferred representations of special symbols which are not words, in the IBM PL/1 60-character set, and in the Model 33 Teletype set, are as follows:

#### Special symbol PL/1 Teletype

{	(*	(*
}	*)	*)
↑	@	↑
break	-	\

Programs can be converted from one representation to another by a finite-state algorithm which recognizes each special symbol and identifier in the source representation, and outputs the corresponding symbol in the target representation. During this conversion, break characters can be supplied arbitrarily. The recommended strategy for break characters is as follows:

- If neither representation has lower case, or both do, break characters should be preserved.
- If only the source has lower case, a break character should be inserted between a lower case letter and a following upper case letter in an identifier.
- If only the target has lower case, all letters should be converted to lower case, except that when a letter follows a break character, the break character should be dropped and the letter left in upper case.

### 13.2 Standard format for programs

It is strongly recommended that an implementation include an option to produce a version of the source program in a standard format. The recommended standard is:

One level of indentation for each unmatched **begin**, **record**, **module**, **loop**, **if**, or **case**. The bracket and its corresponding **end** should also be indented, except in the case of **if .. elseif .. else**, and **case**. The **for** clause should not be indented. Indentation should be omitted if the entire compound statement or declaration will fit on one line. Thus

```
a := 3; a1 := 31; a2 := 32
      begin
        b := 4
      end
      c := 5
      if b=4 then
        a := 6
      else
```

```
a := 7
end if
if b=4 then a := 6 else a := 7 end if
    loop
    ...
    end loop
for i in 0..5
    loop
    ...
    end loop
```

A second level of indentation for the scope in each case element. Thus

```
case a of
    3 =>
        OutputLine(a, b, 100)
        InputLine(a, b, 100)
    end 3
    4 =>
        OutputLine(a, b, 200)
        InputLine(a, b, 200)
    end 4
end case
```

If a statement is too long for one line, it should be continued on subsequent lines with a small amount of indentation (one or two spaces).

Several short statements may be put on the same line.

Semicolons should be omitted at the ends of lines, if they are supplied automatically by the compiler, as they nearly always are (see 3.1).

### 13.3 Annotation

It is strongly recommended that an implementation include an option to produce an annotated listing of the source program, in which all identifiers automatically imported into a closed scope and the formal parameter declarations corresponding to uses of parameter are noted.

## 14. Implementation notes

*"The horror of that moment,' The King went on, 'I shall never, never forget!'  
'You will, though,' the Queen said, 'if you don't make a memorandum of it.'"*  
*Through the Looking-Glass, Ch. 1*

This section discusses implementation techniques for parts of the Euclid language which are relatively new or tricky. Of course, no implementation is required to use these techniques.

### 14.1 Identifiers

Identifiers may vary in capitalization, and in the presence or absence of break characters. The Euclid rule is that each time an identifier is used, it must be written the same way it was declared (see 3.). This rule can be efficiently enforced by normally looking up the identifier exactly as it is written, and making the more expensive comparison which ignores break characters and capitalization only when adding an identifier to the symbol table. If a hash table is used, the hashing algorithm should probably be chosen to map equivalent identifiers into the same hash code.

An alternative implementation is to store the identifier in a standard case, with break characters removed, and to append to it the additional information needed to keep track of the case of each letter, and the presence of break characters.

### 14.2 Parsing

Euclid has been designed to be amenable to LALR parsing [Aho and Johnson 74]. The syntax presented in the body of the report is not LALR, since it was chosen primarily to aid the reader and facilitate the exposition, but a LALR grammar which generates the same language can be obtained from the System Development Corporation (see Preface).

### 14.3 One-pass translation

Euclid has been designed to permit one-pass translation. To this end, identifiers must be declared before they are used. Recursive routines and types may break this rule by using forward for the definition, but all the type information must still be present before use.

### 14.4 Routine parameters

Constant parameters can be passed either by copying the value, or by reference, i.e., by passing the address of a variable containing the value, unless the variable overlaps some variable accessible in the routine, in which case the parameter must be passed by copying. The same test can be used to detect this overlap which is required to detect the overlap of two variables; it depends on the definition of overlap given in section 7. Note that imported variables must be treated exactly like variable parameters for this test.

Variable parameters can be passed either by passing the address of the variable, or by copying the value on entry to the routine, and copying it back on exit; the latter copying is unnecessary if it is readonly. The absence of overlap means that this double copying will always work. If a variable is passed by double copying, then a constant parameter whose

value is an overlapping variable can safely be passed by reference; this might be desirable if the constant is much larger than the variable.

#### 14.5 Routines in modules

If a routine  $R$  is declared in a module  $M$ , and  $R$  imports a non-manifest component  $c$  of  $M$ , then  $R$  must obtain access to  $c$  when it is called. The call must take the form  $m.R(...)$ , where  $m$  is a variable or constant of type  $M$ . This may be done in two ways:

By passing  $m$  (presumably by reference), and treating  $m$  as a record within  $R$ ;  $c$  would then be accessed by its known position relative to the address of  $m$ .

By passing  $c$  explicitly. This might be preferable if it is the only such component.

If  $R$  imports only manifest constants, everything can be done at compile-time. If it imports any non-manifest component  $c$ , however,  $c$  must in general be passed as a parameter, since it could be different for different module variables. There is one exception: if  $R$  imports only constants which depend only on constants declared in module types for which only one variable is ever created, then the references to these constants can be compiled into  $R$ , and they need not be passed as parameters.

#### 14.6 Constant components of records and modules

The same observations apply in general to constant components. Except under the conditions described above, a constant component or parameter must be stored in each variable, since it may be different from one variable to another. Of course, if the component or parameter is never referenced, except during initialization, then it need not be stored.

#### 14.7 Finalization

If a scope declares a module variable which includes a finalization statement, then code must be executed whenever the scope is exited which performs the finalization. This might be done inline, or by calling a routine. The same is true whenever a Free procedure is executed to free such a variable.

Since this machinery must be present anyway, it can be used to allow variables declared in the scope, whose size is not manifest, to be allocated someplace other than in the frame of the routine containing the scope. The finalization code for the scope would then be expanded to include code for freeing the storage used by such variables. Whether this technique is worthwhile depends on the allocation strategy used for frames.

#### 14.8 Inline code

In general, it is highly desirable for an implementation to consider the use of inline code for all short routine bodies, even if the program has not explicitly declared them inline. It is quite common for such bodies to be shorter than their calling sequences, especially since they can be subjected to normal optimization once they have been inserted inline.

### 14.9 Reference counts

There is an important special case in which it is possible to avoid incrementing and decrementing reference counts. Suppose that the program has a declaration

type  $C$  = counted collection of ...

We say that a scope  $S$  is  $C$ -conservative if it contains no assignments to variables of type  $\uparrow C$  which are not local to  $S$ , and if furthermore any routines which  $S$  calls are also  $C$ -conservative. Within  $S$  it is not necessary to update reference counts for variables in  $C$ , since no variable in  $C$  can be freed in  $S$ , and every such variable will have the same reference count on exit from  $S$  that it had on entry to  $S$ . This idea can be extended to routines which make assignments to variable parameters of type  $\uparrow C$ .

### 14.10 Representation of pointers

It is possible to take advantage of the fact that pointers are strictly segregated by collection, to make the representation of a pointer depend on the collection it is in. For instance, a pointer could be relative to some base address. Of course, such a representation cannot be used in a sensitive context.

### 14.11 Parameterized types

Suppose  $T$  is a parameterized type. With two exceptions, it is not necessary to store the parameters of a variable of type  $T$  with the variable. These exceptions (see 6.3) are

$T$  has an actual parameter **any**;

the variable is in a collection whose object type contains **unknown**.

In all other cases, the values of the parameters are known from the declaration. If the declaration contains **parameter**, it must be in a formal parameter list, and the value can be passed as an additional formal (see 10.). If the type is exported from a module, it may import components of the module, in which case the remarks of 14.5 are applicable.

These considerations are especially relevant for variant records and arrays. A variant record is normally used in one of three ways:

- a) To express the uniformity of several different record structures, even though the particular structure in use is always manifest from the declarations.
- b) When the variant is expected to change during execution. A variable of this kind must be declared with **any**, and the tag must be stored in the record. Furthermore, enough space must be allocated for the largest of the possible variants.
- c) When the variable is dynamic, and the variant is fixed at the time the variable is created. A collection of such variables must be declared with **unknown**, and the tag must be stored with each variable, or with each pointer.

The third case, involving **unknown**, is also appropriate for arrays. For example, there might be a collection of strings of widely varying length, all of which should be treated uniformly.

When one of the bounds of an array is a parameter, the size of the resulting type is not known at compile-time; such a type is called *length-unresolved*. If more than one length-unresolved variable is declared in a record or routine, it is not possible to determine

the position of every such variable at compile-time. This situation can be dealt with by constructing pointers to all the length-unresolved components except the first one at the time the record variable or routine instance is created, and referring to them indirectly through these pointers.

## Appendix B. Zone Example

The following type implements zones for allocating fixed-size cells from a free storage list. It makes critical use of unchecked type conversions, of the built-in type, AddressType, of StorageUnit.Address, and of machine-dependent records.

```

type ListZone(pervasive nCells, cellSize, cellAlignment: unsignedInt) =
  machine dependent module exports(nFreeCells)
    {this module provides a zone for allocating and deallocating list
     cells of size cellSize}

  {definition needed by the compiler to process this module as a zone}
  type AllocUnit = machine dependent record aligned mod cellAlignment
    var theStorage (at 0): StorageUnit
    var theRest (at 1): array 1..cellSize-1 of StorageUnit
  end AllocUnit

  var storageBlocks: collection of AllocUnit
  type SBPtr = ↑storageBlocks

  type FreeCell = forward
  var cellCollection: collection of FreeCell
  type CellPtr = ↑cellCollection

  type FreeCell =
    machine dependent record aligned mod cellAlignment
    var link (at 0): CellPtr
    var theRest (at CellPtr.size):
      array 1..cellSize-CellPtr.size of StorageUnit
    end FreeCell

  var freeListHead: CellPtr
  var nFreeCells: 0..nCells := nCells

  procedure Allocate(s, a: unsignedInt, var p: SBPtr) =
    imports (var nFreeCells, SBPtr<=>CellPtr, storageBlocks,
            var freeListHead, cellCollection)
    pre s=cellSize and a=cellAlignment; post nFreeCells in 0..nCells-1
    begin
      if nFreeCells = 0 then
        p := storageBlocks.nil
        return
      end if
      nFreeCells := nFreeCells-1
      p := SBPtr<=>CellPtr(freeListHead)
      freeListHead := freeListHead↑.link
    end Allocate

  procedure Deallocate(p: SBPtr, s: unsignedInt) =
    imports (var nFreeCells, CellPtr, CellPtr<=>SBPtr,
            var freeListHead, var cellCollection, storageBlocks)
    pre s = cellSize and
        nFreeCells in 0..nCells-1 and p not= storageBlocks.nil
    post freeListHead not= cellCollection.nil and nFreeCells in 1..nCells
    begin
      var cp: CellPtr := (CellPtr<=>SBPtr(p))
      cp↑.link := freeListHead; freeListHead := cp
      nFreeCells := nFreeCells+1
    end Deallocate

```

```

var space: machine dependent record aligned mod cellAlignment
var block (at 0): array 0..nCells*cellSize-1 of StorageUnit
end space

initially {set up the free list}
imports(space, CellPtr, CellPtr<=AddressType,
        var freeListHead, var cellCollection)
post freeListHead not= cellCollection.nil
begin
function MakeCellPtr(i: space.block.IndexType) returns CellPtr =
    imports(CellPtr<=AddressType) pre cellSize >= CellPtr.size
    begin
    const a: AddressType := StorageUnit.Address(space.block)
    return (CellPtr<=AddressType(a+i*cellSize))
    end MakeCellPtr

var ci: CellPtr := MakeCellPtr(0)
freeListHead := ci {pointer to first FreeCell}
for i in 0..nCells-2
    loop const cNext := MakeCellPtr(i+1)
    ci^.link := cNext
    ci := cNext
    end loop
ci^.link := cellCollection.nil {mark the end of the free list}
end

invariant nFreeCells in 0..nCells

finally {all cells should be free}
imports (nFreeCells, FreeListHead, cellCollection)
pre nFreeCells=nCells and freeListHead not= cellCollection.nil
begin
end
end ListZone

```
